ABSTRACT

Electron transfer from all respiratory chain dehydrogenases of the electron transport chain (ETC) converges at the level of the quinone (Q) pool. The Q redox state is thus a function of electron input (reduction) and output (oxidation) and closely reflects the mitochondrial respiratory state. Disruption of electron flux at the level of the cytochrome *bc*₁ complex (cIII) or cytochrome *c* oxidase (cIV) shifts the Q redox poise to a more reduced state which is generally sensed as respiratory stress. To cope with respiratory stress, many species, but not insects and vertebrates, express alternative oxidase (AOX) which acts as an electron sink for reduced Q and by-passes cIII and cIV. Here, we used *Ciona intestinalis* AOX xenotopically expressed in mouse mitochondria to study how respiratory states impact the Q poise and how AOX may be used to restore respiration. Particularly interesting is our finding that electron input through succinate dehydrogenase (cII), but not NADH:ubiquinone oxidoreductase (cI), reduces the Q pool almost entirely (> 90%) irrespective of the respiratory state. AOX enhances the forward electron transport (FET) from cII thereby decreasing reverse electron transport (RET) and ROS specifically when non-phosphorylating. AOX is not engaged with cI substrates, however, unless a respiratory inhibitor is added. This sheds new light on Q poise signaling, the biological role of cII which enigmatically is the only ETC complex absent from respiratory supercomplexes but yet participates in the tricarboxylic acid (TCA) cycle. Finally, we delineate potential risks and benefits arising from therapeutic AOX transfer.

1. Introduction

Mitochondria are cellular organelles with vital functions that range from ATP production and redox homeostasis to cellular signaling. Consequently, mitochondrial dysfunction is present in a number of the most threatening human pathologies including neurodegenerative [1] and cardiovascular diseases [2,3], obesity, diabetes mellitus [4,5], malignant cell transformation [6–8] and septic organ failure [9].

A key component for mitochondrial functions is the electron transport chain (ETC) which consists of four multi-subunit protein

complexes and their redox partners. *i.e.* the quinone (Q) pool and cytochrome *c*. NADH:ubiquinone oxidoreductase (cI) and succinate dehydrogenase (cII) facilitate substrate oxidation and Q pool reduction (quinone-reducing complexes) whilst cytochrome *bc*₁ complex (cIII), cytochrome *c* and cytochrome *c* oxidase (cIV or COX) are the quinol-oxidizing components of the ETC. Notably, substrate oxidation and transfer of reducing equivalents through the ETC is coupled to tricarboxylic acid (TCA) cycle activity *via* cII and, in addition, to the generation of a proton-electrochemical gradient by the respiratory complexes cI, cIII and cIV. The mitochondrial membrane potential ($\Delta\psi$)

is the major component of the proton-electrochemical gradient which itself is indispensable for ATP generation and mitochondrial redox homeostasis. Therefore, electron transfer from all respiratory chain dehydrogenases converges at the level of the Q pool and controlled electron flux through the ETC is the basis for metabolic homeostasis. Conversely, any blockade of cIII and cIV results in the Q pool becoming highly reduced thereby disturbing metabolic homeostasis and decreasing cellular viability [10,11]. Consequently, controlling the Q reduction state affects $\Delta\psi$ and ATP production and is of vital importance and decisive for health or disease. To cope with respiratory impairment, many species, but not insects and vertebrates, express alternative oxidase (AOX), a di-iron carboxylate protein which oxidizes the Q-pool in a non-protonmotive fashion [12] thereby acting as an electron sink for reduced Q and by-passing cIII and cIV. Such a by-pass of impaired ETC complexes by xenotopic expression of AOX has been suggested to alleviate diseases, if not offer a cure [13–15].

In previous studies, the presence of AOX in models in which ETC complexes have been disrupted has proved beneficial in restoring respiratory activity and correcting metabolism in cultured mammalian cells [16–18], fruit flies [19–22] and mice [23]. Furthermore, AOX conferred resistance to cyanide toxicity [24,25] and decreased lethality from sepsis [26]. Confusingly, AOX expression, however, had detrimental consequences in a mouse model of mitochondrial myopathy [11]. We thus sought to revisit mechanisms of ETC control in an attempt to determine how AOX expression interferes with mammalian bioenergetics. Using isolated heart mitochondria from mice xenotopically expressing *Ciona intestinalis* AOX [25], we show that respiratory activity of cII, but not cI, causes a rapid reduction of Q ($Q_r > 90\%$) of total Q (Q_t). Importantly, a high Q_r/Q_t state is a condition favoring reverse electron transport (RET) [10,57], a signaling event of pathophysiological relevance, but has only a marginal impact on forward electron transport (FET). In different species, a high Q_r/Q_t state has also been identified as a pre-requisite for the engagement of AOX activity [27,28].

Here, the use of AOX revealed the extent to which the interplay of the dehydrogenases and oxidases defines the direction of electron flow (*i.e.* RET or FET). Our results also raise the question as to the legitimacy of the dual function of cII acting both, as an ETC complex and a member of the TCA cycle. Finally, the results presented in this study underline the potential benefits and risks that AOX expression may have as a diagnostic tool and/or treatment option.

2. Materials and methods

2.1. Mouse model

Ciona intestinalis alternative oxidase (AOX) coding sequence was knocked into the genomic mouse *Rosa26* locus. AOX expression was controlled by a ubiquitous and strong CAG promoter [25]. Part of the animal experiments were conducted under the 1986 UK Animals (Scientific Procedures) Act and approved by Home Office licenses (PPL: 7538 and P6C97520A) and local ethical review. All mice were kept on a C57Bl6, and WT littermates were used as controls. Animals were maintained in a temperature- and humidity-controlled facility, with a 12-h light/dark cycle and free access to water and food.

2.2. Isolation of heart mitochondria

Heart mitochondria from 12 to 18-week-old mice were isolated as described [29]. Briefly, hearts were rapidly removed and transferred to ice-cold MMSE-A buffer (225 mM D-mannitol (Sigma-Aldrich, M4125), 20 mM MOPS (Sigma, M1254), 75 mM sucrose (Sigma, S7903), 1 mM ethylene glycol-bis(2-aminoethylether)-N,N,N',N'-tetraacetic acid (EGTA, Sigma-Aldrich, E4378), 0.5 mM DL-dithiothreitol (DTT, Sigma, 43819), pH 7.4). All further steps were performed on ice. Heart tissues were minced using scissors and manually potted in a glass-on-Teflon

homogenizer until homogenous in MMSE-B buffer (MMSE-A buffer plus 0.05% nagarse, Sigma, P8038). Nagarse activity was stopped by 1:30 dilution of the homogenate in MMSE-A buffer. The homogenate was centrifuged at 2000 $\times g$ for 4 min at 4 °C and the supernatant passed through cheesecloth. The flow-through was centrifuged at 12,000 $\times g$ for 10 min at 4 °C and the pellet resuspended in ice-cold MMSE-C buffer (225 mM D-mannitol, 20 mM MOPS, 75 mM sucrose, 0.1 mM EGTA, 75 mM KCl, pH 7.4). Mitochondrial protein content was estimated using bicinchoninic acid assay (Pierce BCA Protein Assay Kit, Thermo Scientific, 23225) with bovine serum albumin used as standard.

2.3. Blue-native (BN) gel electrophoresis

Blue-native (BN) and BN/BN gel electrophoresis, complex I in-gel activity staining and sample preparations were performed as previously described [30,31] using ~3% digitonin (Serva, 19551) and 0.02% n-dodecyl β -maltoside (GLYCON Biochemicals, D97002-C) as detergents.

2.4. Western blot analysis

Blue-native (BN)/BN gels were blotted onto polyvinylidene difluoride (PVDF) membranes as described [30] and probed with custom-made AOX anti-serum (1:10,000; 21st Century Biochemicals) [17]. Goat anti-rabbit IgG (whole molecule)-Peroxidase antibody (Sigma, A0545) served as secondary antibody. Enhanced chemiluminescence (ECL) was used and the signal detected in a ChemiDoc XRS (Bio-Rad).

2.5. Complexome profiling

A first dimensional BN electrophoresis gel was stained with Coomassie Brilliant Blue G 250 (Serva, 17524) and the appropriate lane was cut into 96 fractions. Proteins in the gel fractions were digested using trypsin (Promega, V5111) and analyzed by mass spectrometry (MS) essentially as described [32]. MS data were analyzed by MaxQuant (v1.5.2.8) [33]. Proteins were identified using a mouse reference proteome database UniProtKB released in 6/2015 supplemented with *Ciona intestinalis* AOX. Enzyme specificity was set to trypsin. Acetylation (+42.01) at N-terminus, oxidation of methionine (+15.99), deamidation of asparagine and glutamine were selected as variable modifications and carbamidomethylation (+57.02) as fixed modification on cysteines. The false discovery rate (FDR) for the identification of proteins and peptides was 1%. Intensity-based absolute quantification (iBAQ) values were recorded. Protein abundance within native lanes were normalized to maximum appearance. Slice numbers of the maximum appearance of mitochondrial complex III dimer (483 kDa), complex IV (213 kDa), complex V (538 kDa) and respiratory super-complex containing complex I, III dimer and one copy of complex IV (1676 kDa) were used for native mass calibration. The mass spectrometry proteomics data have been deposited to the ProteomeXchange [34] Consortium via the PRIDE [35] partner repository with the dataset identifier PXD014016.

2.6. Respirometry and mitochondrial ROS measurements

Mitochondrial oxygen consumption was measured using high-resolution respirometry (O2k oxygraph, Oroboros Instruments, Innsbruck, Austria) at 30 °C [36] in air-saturated medium (200 nmol O_2/ml at 95 kPa). Weight-specific oxygen consumption was calculated from the time derivative of the oxygen concentration (DatLab 7 software, Oroboros Instruments, Innsbruck, Austria). Respiration of isolated heart mitochondria (0.03 mg protein per ml) was measured in MMMP-K buffer (120 mM D-mannitol, 20 mM MOPS, 5 mM KH_2PO_4 , 60 mM KCl, 5 mM $MgCl_2$, pH 7.4) in the presence and absence of substrates and inhibitors as described [37]. Briefly, we used complex I substrates 10 mM pyruvate (P, Pyr, Sigma, P5280), 10 mM glutamate (G, Glu, Aldrich, 49621), 2 mM malate (M, Mal, Sigma, M1000);

complex II substrate 10 mM succinate (Succ, Sigma-Aldrich, S2378) in presence or absence of 1.5 μ M rotenone (ROT, Sigma-Aldrich, R8875); adenosine 5'-diphosphate (ADP, Sigma, A2754) as indicated; 5 μ M carboxyatractyloside (CAT, Calbiochem, 21-620), antimycin A (AA, Sigma, A8674) as indicated; azide (Az, Sigma-Aldrich, S2002) as indicated; 1 μ M carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP, Sigma, C2920); 2.5 μ M oligomycin (Sigma, O4876); 100 μ M n-propyl gallate (n-PG, Sigma, P3130).

Mitochondrial ROS production was measured in parallel to oxygen consumption by attaching a fluorometer module to the respirometer and using a probe specific for the detection of H₂O₂ production [38]. Briefly, 10 μ M of Amplex UltraRed Reagent (Invitrogen, A36006), 1 U/ml of peroxidase from horseradish (Sigma, P8250) and 5 U/ml of superoxide dismutase (SOD, Sigma, S8409) were added to the chamber before starting the measurement. The raw fluorescence signal was calibrated to H₂O₂ concentrations of a standard H₂O₂ solution in the presence of isolated heart mitochondria.

2.7. Qr/Qt measurements

Mitochondrial respiration and the level of Q-pool reduction were simultaneously measured voltametrically in a custom-made chamber using an oxygen electrode and a glassy carbon electrode and a platinum electrode connected to an Ag/AgCl electrode for reference essentially as previously described [39].

2.8. Measuring mitochondrial membrane potential ($\Delta\psi$)

$\Delta\psi$ was monitored fluorimetrically using 2 μ M of the $\Delta\psi$ -sensitive probe Safranin O (Sigma-Aldrich, S2255) as described [40]. The fluorescence signal was detected as arbitrary units (a.u.) and the signal after uncoupling with 1 μ M FCCP served as zero value. $\Delta\psi$ is shown as positive value reciprocal to the fluorescence signal.

2.9. Statistical analyses

Statistical analyses were performed using GraphPad Prism (GraphPad Software, version 7.0d). 2way ANOVA was used for comparisons of at least $n = 3$ independent experiments and a P value < 0.05 was considered being statistically significant. All data are shown as mean. Error bars represent standard deviations (SD).

3. Results

3.1. AOX forms homo-oligomers but does not affect the assembly or stoichiometry of other ETC complexes

We first sought to determine if AOX activity requires the recognition of specific interaction partners or if its presence affects the composition or stoichiometries of the native mouse ETC complexes. We studied this using digitonin-solubilized heart mitochondria separated by blue-native (BN) polyacrylamide gel electrophoresis [41,42]. Two mutually complementary strategies were followed. First, we digested individual gel slices by trypsin and performed mass spectrometry analysis to compose a mitochondrial complexome migration profile (Fig. 1A) [32]. In parallel, we incubated BN first dimensions with the more stringent detergent n-dodecyl β -maltoside (DDM) to in-gel dissociate high-molecular weight assemblies [30] and separated DDM-treated lanes in a second dimension (BN/BN) (Fig. 1B,C). Together, both approaches failed to identify AOX interaction partners apart from the previously described homomeric high-molecular AOX assemblies (circles in Fig. 1B,C) [25]. Importantly, AOX did not cluster with any mitochondrial protein or ETC complex with similar migration pattern (Fig. 1A), and ETC complexes showed regular migration patterns, protein composition and supercomplex stoichiometries (Supplementary Table S1; PRIDE dataset PXD014016). Taken together, our data confirm a

xenotopically expressed tunicate AOX in the mouse as a freely diffusible redox partner.

3.2. AOX maintains phosphorylating respiration with cI substrates

A freely diffusible redox partner may pose a metabolic threat if it allows an uncontrolled ETC by-pass since electron flux through the AOX is non-protonmotive [43]. Recent experiments in which trypanosomal AOX allowed maximal NADH oxidation in submitochondrial particles from bovine heart seemingly support this notion [44]. Earlier, we observed that global AOX expression exerts no deleterious effects on the general mouse physiology whilst conferring resistance to systemic cyanide application [25], which may be accounted for by the inability of AOX to effectively compete with cIII for respiratory flux [45]. We tested this assumption in isolated intact mitochondria and found that there was little to no engagement of AOX during cI activity as reflected by the respiratory control index (RCI) of 6.9 ± 1.7 (mean \pm SD, $n = 8$) in wild-type (WT) and 4.9 ± 1.5 ($n = 7$) in AOX mitochondria (Fig. 2A,B) when energized with pyruvate, glutamate and malate (PGM). Such respiration was not sensitive to n-propyl gallate (n-PG), a potent AOX inhibitor. The observed decrease in AOX RCI is based on a slightly higher rate of non-phosphorylating respiration (state 4), *i.e.* respiration upon ADP turnover or upon inhibition of the adenine nucleotide translocase (ANT) by carboxyatractyloside (CAT) (Fig. 2B). This indicates that in the absence of respiratory inhibition only approx. 7% (or 14 nmol O₂/mg/min, blue trace in Fig. 2B) of the total electron flow is diverted to AOX. Another bioenergetic parameter for estimating the efficiency of oxidative phosphorylation is the ADP/oxygen ratio, or P/O value. It refers to the number of moles of ADP phosphorylated to ATP per two electrons flowing through the ETC to oxygen. P/O values for isolated WT and AOX heart mitochondria for different substrate combinations (Supplementary Fig. S1F) are largely in agreement with literature values. Note, inhibition of two proton pumps, *i.e.* cIII and cIV by the addition of cIV inhibitor azide (Az), decreases the P/O value for AOX respiration driven by cI substrates PGM to one coupling site. It should be emphasized, however, that such measurements are notoriously inaccurate as they assume state 4 respiration (the proton leak) ceases during phosphorylating conditions which is obviously not the case when AOX is engaged (Supplementary Fig. S1B). Under these conditions P/O ratios *via* an oxygen electrode are unreliable as the so-called state 4 respiration is too high (~ 200 nmol O₂/mg/min) to distinguish any measurable change in rate upon addition of ADP.

We reasoned that the inability of AOX to be engaged as a terminal oxidase, despite seemingly optimal conditions, may be due to its high K_M for Qr [28]. Therefore, we determined Qr/Qt ratios (in %) in parallel to respiratory rates in WT and AOX heart mitochondria energized by PGM using a Q-electrode [39]. Surprisingly, Qr/Qt values remained low ($\sim 13\%$ Qr/Qt; Fig. 2C) and did not differ despite changing respiratory states. The failure to reach a critical threshold of Qr/Qt (blue horizontal bar in Fig. 2C) [27,28] in principle impedes an AOX engagement. In contrast, under conditions of known Q-pool reduction [28] such as upon cIII (antimycin A, AA) or cIV (azide, Az) inhibition, AOX expression allows respiratory rates in excess of 200 nmol O₂/mg/min (blue traces in Fig. 2E,F; Supplementary Fig. S1A,B). Moreover, inhibitor titrations in AOX-expressing mitochondria resulted in a non-linear dependency of the respiratory rate as the levels of Qr increase [28] under non-phosphorylating conditions (Fig. 2F; Supplementary Fig. S1B). The fact that AA and Az evoked similar responses make unspecific toxic inhibitor effects unlikely and Qr release due to a loss of supercomplex integrity was ruled out by measuring cI activity on a BN gel (Supplementary Fig. S1C). Importantly, despite being non-protonmotive [43], AOX indirectly maintained $\Delta\psi$ in PGM energized mitochondria in the presence of AA (Fig. 2D) [46]. Such a finding is substantiated by the result that subsequent addition of cI inhibitor rotenone (ROT) collapses $\Delta\psi$ (Fig. 2D). This demonstrates that AOX can act as an effective electron sink *in vivo* allowing phosphorylating (state

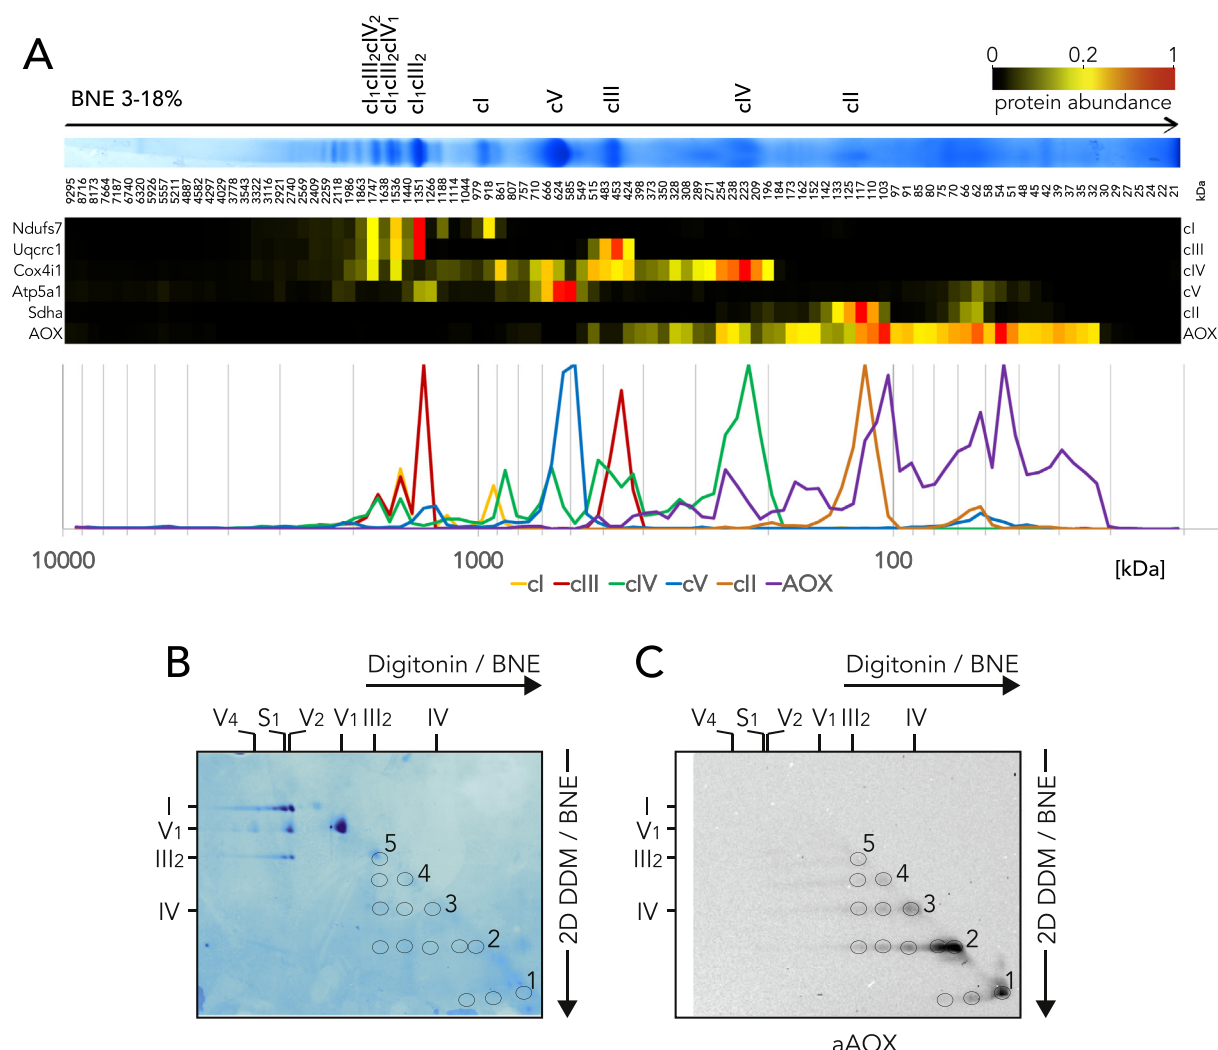

Fig. 1. AOX acts as a freely diffusible Qr redox partner. (A) Digitonin-solubilized AOX heart mitochondria separated by 1D blue-native (BN) polyacrylamide gel electrophoresis, analyzed by mass spectrometry. Heat maps of selected protein subunits representing individual respiratory complexes with red color representing a high and black color representing a low expression. cI, Ndufs7; cIII, Uqcrc1; cIV, Cox4i1; cV, Atp5a1; cII, Sdha. Line-chart to illustrate the migration pattern of classical respiratory complexes and AOX assemblies. Note, estimated molecular masses support the notion that AOX expressed in the mouse assembles into homooligomers mainly consisting of multimers of dimers. (B) Coomassie stain of digitonin-solubilized AOX heart mitochondria separated by tandem BN/BN using n-dodecyl β -maltoside (DDM) treatment before second dimensional run. (C) AOX protein detected by western blot analysis. Of note, the regular pattern of AOX assemblies marked by circles again indicates that AOX does not form erratic aggregates but rather assembles into multimers of different stoichiometries. Circles from the western blot analysis have been superposed onto the Coomassie stained gel to visualize the AOX multimer migration pattern in comparison to other mitochondrial complexes.

3) respiration on cI substrates when electron flux through the ETC downstream of Q is blocked.

3.3. AOX facilitates succinate-dependent FET under high protonmotive force

Similar to AOX, cII is also non-protonmotive and succinate oxidation has previously been shown to rapidly increase Qr/Qt levels to approx. 90% [28]. Since succinate is a TCA substrate, it is plausible that cII and AOX together may form a futile respiratory cycle with detrimental consequences on cell viability. Our previous results suggest that an activation of such futile cycle does not happen in the AOX mouse under non-stressed conditions [25]. To understand the mechanistic basis for this paradox, we energized isolated heart mitochondria with succinate and measured respiratory rates in the presence of ROT (Fig. 3A). Our data reveal that succinate rapidly reduces the Q-pool above a critical threshold (blue horizontal bar in Fig. 3B) without generating relevant amount of mitochondrial reactive oxygen species (ROS) under any respiratory state (Fig. 3C) and that the presence of

AOX does indeed enhance mitochondrial respiratory rates both under phosphorylating (presence of ADP, state 3) and non-phosphorylating (absence of ADP, state 4) conditions (Fig. 3A). Diversion of electron flux through AOX is also reflected by a decrease in RCI from 3.2 ± 0.5 (mean \pm SD, $n = 5$) in WT to 1.3 ± 0.1 ($n = 7$) in AOX mitochondria (Supplementary Fig. S1D,E). Interestingly, the respiratory rate has little, if any, effect on the Qr/Qt ratios (Fig. 3B). Similar to cI substrates, $\Delta\psi$ is still maintained during succinate-driven respiration (Fig. 3D), suggesting that even in the presence of AOX, a significant proportion of the electron flux is mediated via the proton-pumping activities of cIII and cIV (representative traces shown in Fig. 3E,F). P/O values were also calculated for succinate-dependent respiration in WT heart mitochondria (Supplementary Fig. S1F). As indicated previously, AOX activity is a complicating factor during succinate-dependent respiration (both in the presence and absence of ADP, respectively). This prevents any accurate calculation of P/O values with AOX respiring mitochondria. In support of such a notion, it is apparent from the original respiratory traces (Supplementary Fig. S1D,E) that the P/O ratio of isolated AOX

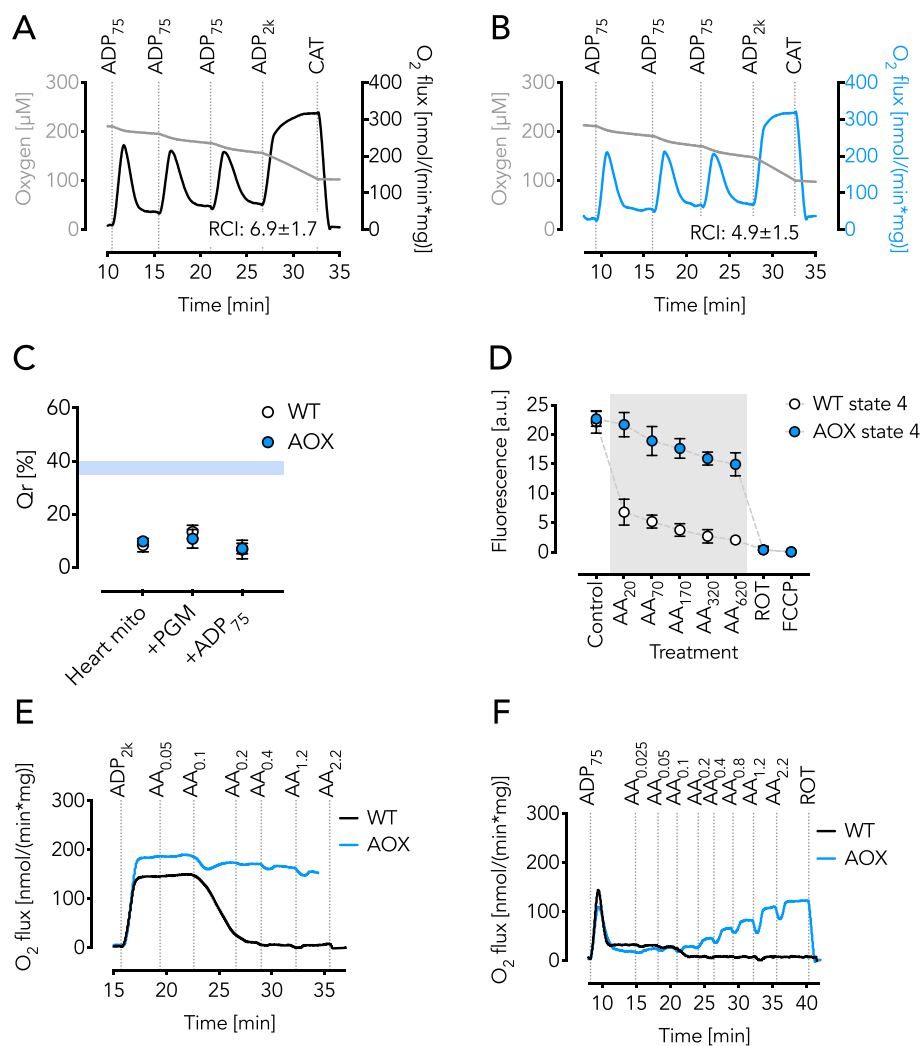

Fig. 2. AOX is engaged on cI substrates only in the presence of respiratory inhibitors. Representative respirometry traces of isolated WT (A) and AOX (B) heart mitochondria respiring on cI substrates pyruvate, glutamate and malate (PGM) with adenosine diphosphate (ADP in μM) and carboxyatractyloside (CAT) additions as indicated. Respiratory control indices (RCI) shown as mean \pm SD, WT $n = 8$, AOX $n = 7$. (C) Qr/Qt ratios (%) shown as mean \pm SD, $n = 3$. Blue horizontal bar represents putative threshold for AOX engagement. (D) Mitochondrial membrane potential ($\Delta\psi$) shown as arbitrary units (a.u.) as mean \pm SD, $n = 3$. AA, antimycin A. heart mitochondria must be significantly lower than in WT even if an accurate number cannot be reliably determined because of the high basal respiratory rate.

3.4. AOX prevents RET under non-phosphorylating conditions

Succinate accumulation along with high $\Delta\psi$ and Qr/Qt has been described as mechanism for RET [10] in ischemia-reperfusion injury and inflammatory diseases [26,47,48]. For the latter, AOX was demonstrated to have beneficial effects [26]. The bioenergetic rationale for such beneficial effects was believed to depend upon the ability of AOX to maintain the Q-pool in a more oxidized state in comparison to WT mitochondria thereby reducing RET-mediated ROS production [10,25]. We sought to test if this was the case by determining how AOX exerts its effects on mitochondrial respiration on succinate in the absence of ROT and thus in the presence of a fully functional cI. Again, isolated heart mitochondria expressing AOX were used and we discovered enhanced succinate-driven respiration under non-phosphorylating conditions (Fig. 4A; Supplementary Fig. S1G). Although the addition of small amounts of ADP increased respiration in WT mitochondria, the presence of AOX had no additive effect (Fig. 4A; Supplementary Fig. S1G). The addition of saturating amounts of ADP failed to induce sustained phosphorylating respiration (Fig. 4A; Supplementary Fig. S1G) both in WT and AOX heart mitochondria. This was previously attributed to a loss of $\Delta\psi$ and the generation of the potent cII inhibitor oxaloacetate [49]. As demonstrated here (Fig. 4D), such a notion is not supported by $\Delta\psi$ measurements (original traces shown in

Fig. 4E,F). Although addition of ADP severely diminished the magnitude of $\Delta\psi$, the fact that it is restored upon ANT inhibition by CAT (Fig. 4D), suggests that the observed depolarization is due to ATP/ADP exchange and not due to a proposed inhibition of cII activity [49]. In support of this notion, respiratory uncoupling by carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP) following CAT fully depolarizes $\Delta\psi$ (Fig. 4D–F). Furthermore, measurements of the steady-state redox poise of the Q-pool in the absence of ROT showed that the pool is highly reduced irrespective of the respiratory state and presence or absence of ADP and/or AOX (Fig. 4B). Although the subsequent addition of PGM and/or ROT in the presence of succinate dramatically increased respiratory rates (Fig. 4A; Supplementary Fig. S1G) addition of ROT caused negligible Q oxidation (Fig. 4B). Of particular importance is the observation that the presence of AOX, in the absence of ROT, substantially reduces ROS production in comparison to WT mitochondria (Fig. 4C; Supplementary Fig. S1H) both in the presence of succinate alone or under non-phosphorylating conditions. Such results indicate that under pathologic conditions, AOX can shift the electron flux through the ETC from RET (and ROS) towards FET.

4. Discussion

In the present study, we confirm that AOX from the tunicate *Ciona intestinalis* functions as a freely diffusible mitochondrial oxidase potentially without mobility restrictions when xenotopically expressed in the mouse (Fig. 1A). This may seem surprising considering the formation of high-molecular weight assemblies which have previously been

described as mainly homo-oligomers of dimers [25]. Indeed, it is unclear thus far, which assembly stoichiometry may constitute the most active AOX form in the mouse *in vivo*. Interestingly, the expression of AOX as dimer was first described for plants and its reduction state was related to its catalytic activity [50]. Later it was proposed that AOX dimerization is common to all AOXs and that such assemblies may be of mechanistic or structural importance [12,51,52]. Respiratory stress may result in the buildup of reducing equivalents within the mitochondrial matrix thereby facilitating the reduction of regulatory residues, e.g. cysteines forming disulfide bonds [50]. It is unlikely, however, that this mechanism controls AOX activity in its host *Ciona intestinalis* since this tunicate AOX does not contain the conserved cysteine residues necessary for activation as is the case in plants. How homo-oligomerization of xenotopically expressed tunicate AOX in the mouse affects its catalytic engagement cannot be concluded with absolute certainty to date, however, it is obvious from this and previous studies that a xenotopically expressed tunicate AOX is highly active. Furthermore, apart from the formation of homo-oligomers, AOX association with supercomplexes has never been demonstrated although it is conceivable, albeit unlikely, that the inclusion of digitonin may have removed AOX from high-molecular structures. Altogether, this supports the notion that xenotopically expressed AOX acts as a freely diffusible redox partner. Indeed, when trypanosomal AOX was added to sub-mitochondrial particles (SMPs) in the presence of cyanide, respiratory activity was restored [44] from which it was concluded that Q channeling in mitochondrial supercomplexes does not exist. We found,

however, that in isolated mouse heart mitochondria respiring on cI substrates in the absence of respiratory inhibitors AOX only marginally affected the RCI suggesting that under these conditions AOX was barely engaged (Fig. 2B). Such a lack of engagement was substantiated by the discovery that in the absence of respiratory inhibitors the Q-pool is insufficiently reduced by cI to maintain AOX activity (Fig. 2C). Addition of respiratory inhibitors, however, engages AOX both under phosphorylating (state 3) [25] and non-phosphorylating (state 4) conditions (Fig. 2E,F; Supplementary Fig. S1A,B) whilst maintaining $\Delta\Psi$ (Fig. 2D). Of course, the measured global Q_r/Q_t ratio cannot exclude different local Q_r/Q_t conditions, for instance in a putative compartment within respirasomes between cI and cIII [53]. The fact that AOX and Q are freely diffusible, yet cI substrates do not support high AOX respiration, however, indicate that such high Q_r/Q_t ratios are not achieved or immediately decreased through oxidation by cIII. Titration of cI activity with AA or Az, however, resulted in an exponential increase in the presence of AOX (Fig. 2F; Supplementary Fig. S1B) suggesting that the pool is accessible to AOX under all Q_r/Q_t ratios. This is of importance for the biological function of AOX, e.g. during stress response. It has recently been shown in its natural host, *Ciona intestinalis*, that AOX transcript levels are upregulated upon exposure to hypoxia and by sulfide, a potent cIV inhibitor, whilst being unresponsive to other environmental stressors such as physiologically stressful temperature or heavy-metal exposure [54]. Here, due to the genetic design, AOX transcript level cannot directly correlate with its catalytic function. In fact, our results explain the lack of a detrimental phenotype when AOX

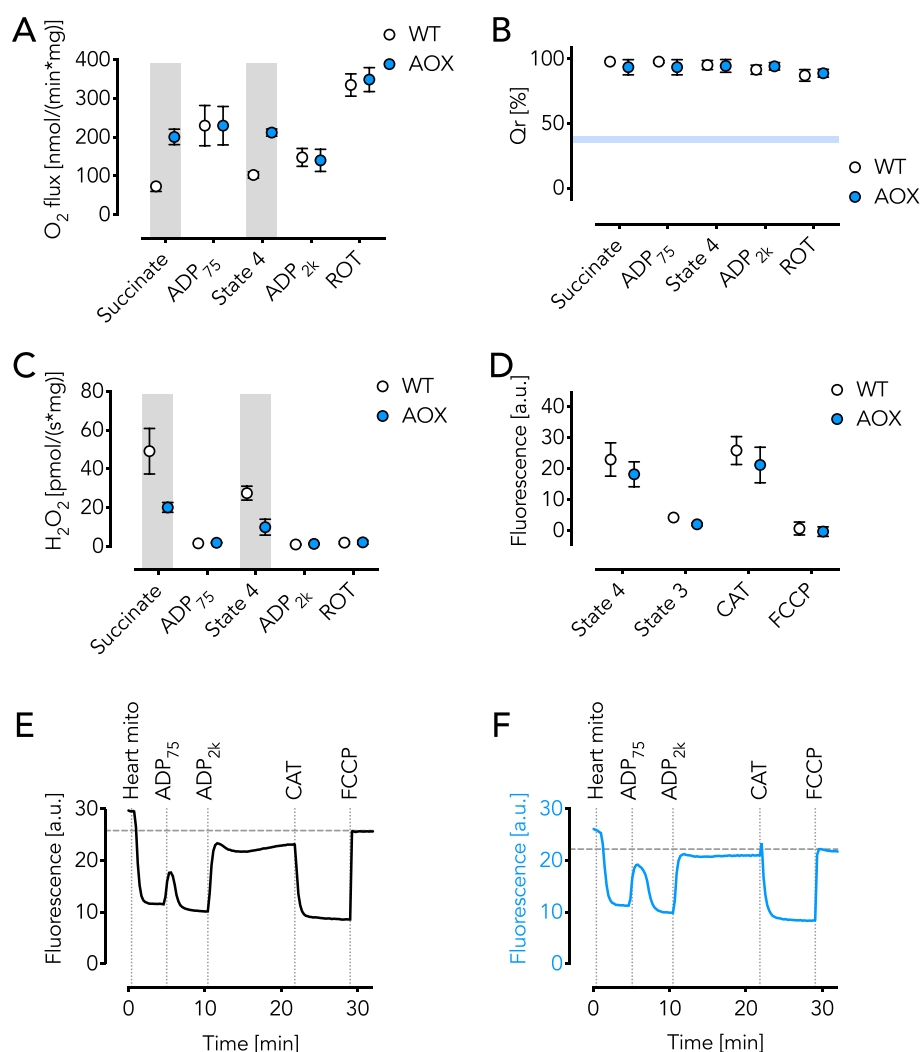

Fig. 4. AOX engages on cII substrate succinate only under non-phosphorylating conditions. (A) Respiratory rates of isolated heart mitochondria shown as mean \pm SD, $n = 3$. ADP in μ M; ROT, rotenone. Grey areas indicate significant difference between WT and AOX ($P < 0.05$) analyzed by 2way ANOVA with post-hoc Sidak's multiple comparisons test. (B) Qr/Qt ratios (%) shown as mean \pm SD, $n = 3$. Blue horizontal bar represents putative threshold for AOX engagement. (C) Hydrogen peroxide production shown as mean \pm SD, $n = 3$. Grey areas indicate significant difference between WT and AOX ($P < 0.05$) analyzed by 2way ANOVA with post-hoc Sidak's multiple comparisons test. Note the inverse relation of hydrogen peroxide production and respiratory rate. (D) Mitochondrial membrane potential ($\Delta\Psi$) using safranin O shown as mean \pm SD, $n = 3$. Note the lack of membrane potential restoration in state 3. (E) Representative trace showing $\Delta\Psi$ under conditions as indicated in WT mitochondria. (F) Representative trace showing $\Delta\Psi$ under conditions as indicated in AOX mitochondria. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

protein is ubiquitously expressed in the mouse despite its ability to resist cyanide intoxication [24,25].

Although, AOX confers resistance to cyanide, the failure to rescue a COX15 knock-out in mouse skeletal muscle at first appeared somewhat mysterious. However, it may be explained by the fact that under disease and respiratory stress conditions, the metabolic situation is different. One major difference between the acute application of cyanide and the permanent ablation of COX15 is that the long-term disruption of signaling cascades required for mitochondrial biogenesis and muscle repair may outweigh potential benefits such as a decreased ROS load. In contrast, succinate accumulation and RET induction has been described for the post-ischemic heart and sepsis [26,47] and for the latter AOX expression showed beneficial effects [26]. Of note, all aforementioned examples concentrate on a putative effect of AOX on pathophysiologic conditions whilst seemingly ignoring physiological signals originating from the respiratory chain. In fact, some stress responses related to mitochondrial dysfunction viewed as detrimental thus far, such as ROS emitted from COX15 deficient mitochondria [11], are now recognized as essential for adaptive remodeling, mitochondrial biosynthesis and survival. In other words, mitochondrial ROS may be of vital importance for adaptation and thus having physiological relevance. This is specifically true for oxygen sensing in the pulmonary vasculature [55] and glomus cells of the carotid body [56]. In both cases, signals from the respiratory chain are required, and an increase of the Qr/Qt ratio can safely be assumed or has been demonstrated. It is tempting to speculate how AOX would interfere with oxygen sensing in the two cell types

considering their specific physiological function and what role succinate may play under such conditions. In an attempt to replicate the above-described metabolic situations, we tested AOX heart mitochondria in the presence of succinate plus ROT (to prevent RET) and observed high respiratory activity even in the absence of ADP which, importantly, was associated with a dramatic decrease in the RCI (also seen as high state 4 respiration in Fig. 3A) suggesting that AOX was engaged. Since cII is generally not present in supercomplex assemblies, the observed respiration is likely based on random collision of the three independent freely diffusible redox partners, i.e. cII, the Q pool and AOX. Qr/Qt measurements revealed that in the presence of cII substrate succinate, irrespective of the presence or absence of ROT, another criterion for AOX engagement is fulfilled, namely the presence of high Qr/Qt ratios (Figs. 3B; 4B). In plants, engagement of the alternative respiratory pathway occurs only when Qr/Qt ratios reach critical thresholds of 35–40% (blue horizontal bars in Figs. 2C; 3B; 4B) [27,28]. Previously, *Ciona intestinalis* AOX expressed in mouse skeletal muscle has revealed strikingly similar Qr/Qt values for catalytic engagement [11]. Surprisingly, we found AOX to be regularly engaged during cII respiration under non-phosphorylating (state 4) but not phosphorylating (state 3) conditions although never achieving maximal respiratory rates (Figs. 3A; 4A) suggesting there is some restriction of electron flow. Importantly, our findings demonstrate that any observed restriction of electron flow is not necessarily due to a lack of Q-pool reduction as Qr levels remain high (Figs. 3B; 4B). It may be due to a loss of $\Delta\Psi$ [49] although addition of ADP depolarizes $\Delta\Psi$ which is CAT-

Fig. 5. Graphical overview on AOX engagement. (A) ci substrates do not allow AOX respiration unless cIII and/or cIV are inhibited. AA, antimycin A. (B) ciI substrate succinate readily engages AOX when ci is inhibited (ROT, rotenone) or in the absence of ADP. Note, ROT acts upstream of Q thus being indicative for a ci control mechanism on AOX engagement independent from the Qr/Qt ratio.

insensitive and thus not due to phosphorylation (Figs. 3D–F; 4D–F). Obviously, some electron flux continues to be mediated by cIII as $\Delta\psi$ is still maintained even with AOX. The finding that electron flux through AOX, in the absence of ROT, is very low may suggest that the regulated element may be cII itself, possibly as a result of oxaloacetate accumulation [49]. If AOX is engaged, however, it supports respiration and abolishes mitochondrial ROS production by RET in a similar manner to ADP addition (Fig. 4A,C). Altogether, our data support the notion that *in vivo* succinate is unlikely to be a major respiratory substrate since a non-phosphorylating respiratory shunt (cII-Q-AOX), would inevitably lead to a severe, non-viable, phenotype which is obviously not the case [25].

Interestingly, the Qr/Qt ratios appear unaffected by any changes of the respiratory state (Figs. 2C; 3B; 4B). Thus, although Qr is fully reduced and potentially accessible to AOX, respiration is low under phosphorylating (state 3) yet high under non-phosphorylating (state 4) conditions (Fig. 4A; Supplementary Fig. S1G). A high electron flux through cII in the presence of oxaloacetate is not likely and contrary to expectations a decrease in the Qr/Qt ratio was not observed. More importantly, when ci substrates were added to the mitochondria we observed an increase in phosphorylating, oligomycin-sensitive, respiration and a decrease in ROS production (Supplementary Fig. S1G,H). Such stimulation, however, is not solely dependent on an increase in $\Delta\psi$ or electron flow through ci since ROT addition showed the same result (Fig. 4A,C). This finding raises questions regarding the true function of cII *in vivo* in health and disease. We propose that under disease conditions, cII-induced RET may be a pivotal signal for adaptation. Under all other conditions, regular succinate levels in the presence of ADP, RET and FET seem to be restricted by a number of possible factors, including ci presence and, may be, its catalytic activity. The fact that a minimum of 84% of ci is complexed in respiratory supercomplexes [42] suggests that some sort of Q flux control or Q compartmentalization may be potentially a reason for the development of supercomplexes.

In conclusion, xenotopically expressed tunicate AOX is a freely diffusible redox partner in mouse mitochondria which is catalytically active when the Q pool is highly reduced (summarized in Fig. 5). However, respiratory engagement is favored under non-phosphorylating (state 4) conditions generally described as respiratory stress. AOX thus is an invaluable tool to investigate respiratory control mechanisms and may become a treatment option for mitochondrial pathologies based on respiratory disruption.
