ADDITIONAL INDEX WORDS. *Cynodon dactylon*, sigmoidal model, stolon, sugar, warm-season turfgrass

SUMMARY. Warm-season grasses are not widely accepted in Mediterranean countries because they lose color during the winter months. A study was conducted at the University of Padova (Padova, Italy) to determine whether fall and spring water-soluble carbohydrate (WSC) content in stolons of seeded bermudagrass cultivars (*Cynodon dactylon*) influenced spring green-up in the first year of establishment. Nine bermudagrass cultivars (La Paloma, Mohawk, NuMex Sahara, Princess 77, Riviera, SR 9554, Barbados, Contessa, and Yukon) were seeded in July 2005, and dry weight and WSC content in stolons were measured in Fall 2005 and again in Spring 2006. The percentage of green cover and days needed to achieve 80% green cover (D80) were regressed against November and March values of stolon dry weight and WSC content to determine if they were good predictors of D80. 'Yukon' showed earliest spring green-up by end of April, and 'Princess 77' and 'Riviera' were slowest, needing 43 to 46 days more than 'Yukon' to reach D80. There was a significant inverse relationship between November ($r^2 = 0.57$) and March ($r^2 = 0.77$) WSC content in stolons and D80 for all nine bermudagrass cultivars. These results suggest that bermudagrass cultivars with high WSC in stolons recover more rapidly from dormancy during establishment than those with low WSC content.

Maintaining cool-season grasses in temperate or transitional climate zones has been criticized because of the relatively high irrigation requirements during the summer. As a result, the use of warm-season turf species that require less water than cool-season grasses is encouraged in Mediterranean countries in an effort to reduce water consumption for landscape irrigation. Unlike cool-season grasses, warm-season species such as bermudagrass are cold sensitive and will lose color when dormant during the cooler periods of the year. Although warm-season turf may not provide active growth and green color year round, they can be used successfully in transitional climate zones, even when dormant (Anderson et al., 2007; Patton et al., 2008). However, a winter dormancy period that prevents year-round green color is currently the main

impediment to a more widespread use of warm-season grasses in these transition zones.

Bermudagrass is one of the warm-season turf species that is best suited to transitional zones in Europe (Croce et al., 2004). Over the last few years it has become more widely used in Italy and is grown on athletic fields, parks, and lawns. While athletic turf areas are usually overseeded with cool-season grasses such as perennial ryegrass (*Lolium perenne*) or annual ryegrass (*Lolium multiflorum*) during the fall to provide green cover during winter months (Gaetani et al., 2004, 2007;

Schmidt and Shoulders, 1980), areas that are primarily used during the warmer periods can be managed without overseeding. Winterhardiness and early spring green-up are considered the most important factors in selecting bermudagrass cultivars in transitional zones (Patton et al., 2008; Richardson et al., 2004).

Numerous studies have reported on the significant role of carbohydrates in turfgrass stress tolerance. White (1973) described two major carbohydrate groups in plants, the nonstructural and the structural carbohydrates. Nonstructural carbohydrates include all major reserve constituents such as reducing sugars (glucose and fructose), non-reducing sugars (sucrose), fructosans, and starches. Hemicellulose (pentosans and hexosans) and cellulose are considered structural carbohydrates and do not provide significant reserves (White, 1973). Most of the nonstructural carbohydrates [also referred to as total nonstructural carbohydrates (TNC)] are water-soluble saccharides, but also include larger polysaccharides (starches) that are insoluble in water. Therefore, water-soluble carbohydrates (WSC), or water soluble non-structural carbohydrates represent a subgroup of TNC.

A positive correlation has been reported between TNC and freezing tolerance in turfgrasses (Di Paola and Beard, 1992; Fry et al., 1993; Rogers et al., 1975). Carbohydrates are stored inside the plant during fall when growth and metabolism are slow, which in return improves cold hardiness by reducing the freezing point and delaying or avoiding cell freezing (Stier and Fei, 2008). In the spring, the carbohydrates are used as an energy source to support the renewed shoot growth (Di Paola and Beard, 1992; Rogers et al., 1975).

Differences in cold hardiness among species depend mostly on plant metabolism during the autumn months, which in turn affects TNC accumulation in storage organs. Unlike bermudagrass, cold tolerance in zoysiagrass (*Zoysia japonica*) has been attributed to an increased photosynthetic rate during the cold hardening period (Rogers et al., 1977). However, Dionne et al. (2001) observed that low temperature tolerance in cool-season annual bluegrass ecotypes was not correlated to sugar levels of sucrose and fructan. Similarly, freezing tolerance of warm-season st. augustinegrass (*Stenotaphrum secundatum*) could also not be correlated with TNC content (Fry et al., 1991; Maier et al., 1994).

Rhizomes and stolons are the principal locations of carbohydrate storage in well-established bermudagrass (Dunn and Nelson, 1974). In comparing the relative importance of the two organs, Dunn and Nelson (1974) suggested that carbohydrate content in stolons was more important to the winter survival of these grasses than the content in rhizomes. In a later study, however, Dunn et al. (1980) reported a strong positive correlation between carbohydrate content in rhizomes of 20 mature bermudagrass cultivars and the speed of spring green-up, an indicator of successful winter survival. In contrast, Goatley et al. (1994) reported that while fertility had an effect on spring green-up of mature Tifgreen turf, no correlation between carbohydrate (TNC) content in rhizomes and spring green-up was observed. Munshaw et al. (2006) and White and Schmidt (1990) documented the importance of management practices such as late season fertilization on fall color retention, cold tolerance, and spring recovery of bermudagrass.

All of these studies were conducted on mature bermudagrass, and information is lacking on the role of carbohydrates in the timing and speed of spring green-up during spring after establishment. Although the presence of rhizomes in bermudagrass at the end of the first growing period have been reported (Ahring et al., 1975; Trenholm et al., 1998), more recent studies (Hensler et al., 1999; Munshaw et al., 2001; Richardson et al., 2004, 2005) have all concluded that seeded bermudagrass do not

produce rhizomes during the establishment year. These results concur with our preliminary observations that no rhizomes were produced during the first year of establishment, and suggest that carbohydrates in stolons may play an important role in winter survival and early green-up of newly established bermudagrass. Munshaw et al. (2001) showed a positive correlation between total nitrogen applied to 'Mirage' bermudagrass during establishment and TNC in stolons at the end of the first growing season. The plots were unaffected by winter kill, confirming the importance of TNC in winter survival, but no timing or rate of spring green-up was reported. Early green-up is not only important to ensure successful winter survival of bermudagrass (Ahring et al., 1975), but it also reflects a shorter dormancy period, a feature that would help this grass gain greater market acceptance in transition zones. Numerous studies have investigated the role of nonstructural carbohydrates on cold or freeze tolerance and on fall or spring color (e.g., Dunn et al., 1980; Dunn and Nelson, 1974; Goatley et al., 1994, 1998, 2005; Miller and Dickens, 1996; Munshaw et al., 2001, 2006; Pedreira et al., 2000; Trenholm et al., 1998), and few report on the specific role of WSC content in cold and freeze tolerance and in bermudagrass color in fall and spring (Dunn and Nelson, 1974; Dunn et al., 1980; White and Schmidt, 1989; Zhang et al., 2006). No published studies exist on the importance of

WSC on spring recovery in newly seeded bermudagrass.

To address the gap in knowledge about the role of stolon WSC reserves in regrowth and greening of seeded bermudagrass during and after the first growing season, a study was conducted at the University of Padova (upper transition zone, northern Italy). The objectives of the study were to examine the seasonal trend in WSC content in stolons of seeded bermudagrass during the first year of establishment and during spring after the first winter, and to determine whether the timing of spring green-up and recovery from winter stress was affected by WSC in stolons.

Materials and methods

A field experiment was conducted at the Experimental Farm of Padova University from Nov. 2005 to July 2006 to examine the change in carbohydrate content in stolons of seeded bermudagrass cultivars in response to seasonal variation in temperature of northeastern Italy (similar to U.S. Department of Agriculture plant hardiness zone 8). The climate in the area is considered subcontinental with an annual mean temperature of 12.3 °C and average minimum and maximum temperatures of -5.5 and 32.8 °C. The average annual rainfall is 811 mm and is mostly distributed during the growing season from April to November. Climate data during the investigative period were collected at a weather station in close proximity to the research area (Table 1). Plots

Table 1. Monthly average maximum and minimum air temperature, soil temperature at 100 mm (3.94 inches) depth, and monthly precipitation at the University of Padova research station in Legnaro, Italy, from July 2005 through June 2006.

^z(1.8 × °C) + 32 = °F, 1 mm = 0.0394 inch.

were seeded on 4 July 2005 with bermudagrass cultivars Princess 77, Mohawk, NuMex Sahara, Barbados, Contessa, Riviera, Yukon, La Paloma, and SR 9554. Cultivars were seeded at a rate of 4 g·m⁻² pure live seed on a silty loam. The soil at the site had a pH of 8.1, an organic matter content of 2.3%, a total nitrogen content of 0.13 g/100 g soil, an available phosphorus content of 38.3 mg·kg⁻¹ soil, and an exchangeable potassium content of 178.1 mg·kg⁻¹ soil.

Slow-release fertilizer (20N–2.2P–6.6K) was applied twice in 2005 (August and September) and twice in 2006 (April and June) at a rate of 40 kg·ha⁻¹. During the growing period, plots were mowed weekly with a rotary mower at a height of 27 mm. Supplemental irrigation from a sprinkler system was provided only during the first month of the establishment period. The experimental design was a randomized complete block with four replications and a plot size of 7.2 m² (1.6 m × 4.5 m).

In Nov. 2005 and Mar., May, and July 2006, turf samples measuring 20 cm (length) × 20 cm (width) × 4 cm (depth) were randomly collected from each plot to measure stolon development and WSC in the stolons. Turf samples were washed to remove any soil from the vegetative parts, and stolons were removed from the plugs with scissors and were immediately frozen at –22 °C. The stolons were later freeze-dried and weighed using an analytical balance to determine stolon dry weight in grams per square meter. Water-soluble carbohydrates were then extracted from dried and ground tissue using an 80% ethanol solution followed by a hot water extraction (Suzuki, 1968). Carbohydrates were colorimetrically quantified after reacting with anthrone reagent (Thomas, 1977).

Spring green-up was determined weekly from 1 Apr. to 22 June 2006 by visually assessing the percentage of green color of each plot. A sigmoidal model (GraphPad Prism 5.0 for Windows; GraphPad Software, La Jolla, CA) was used to calculate days of year (beginning 1 Jan. 2006) needed by each plot to reach 80% green color (D80). Stolon dry weight, WSC data, spring green-up, and D80 were subsequently subjected to analysis of variances using SAS Proc Mixed (version 9.2; SAS Institute, Cary, NC)

followed by Fisher's protected least significant difference test to identify significant differences between means. November and March values of stolon dry weight and WSC were regressed against D80 to determine whether the speed of spring green-up could be predicted from stolon dry weight or WSC in fall and spring.

Results and discussion

STOLON DRY WEIGHT. The data analysis revealed significant sampling date × grasses interactions ($P < 0.001$). Data were subsequently analyzed separately for all sampling dates. Stolon dry weight of 'La Paloma', 'Princess 77', 'Riviera', 'SR 9554', 'Barbados', and 'Yukon' plots decreased between Nov. 2005 and Mar. 2006, and continued to decrease for 'Princess 77' and 'Barbados' plots until May (Fig. 1). Compared with other bermudagrass cultivars, Yukon was earliest to significantly increase stolon dry weight (March–May) (Fig. 1). Stolon dry weight in all other cultivars increased later, from May to July. When data were averaged for all cultivars, stolon dry weight quadrupled from 142 to 600 g·m⁻² between May and July 2006. Of all cultivars tested, 'Barbados' showed the greatest spring increase in stolon dry weight (Fig. 1).

WSC CONTENT. A significant interaction effect between sampling date and turfgrasses' WSC was detected ($P < 0.001$), thus, data were analyzed separately for all sampling dates. Figure 2 shows changes in WSC from

Nov. 2005 to July 2006. WSC did not change during the winter months (Nov. 2005–Mar. 2006) for 'La Paloma', 'Mohawk', 'SR 9554', or 'Yukon'. During the same period, WSC decreased in 'NuMex Sahara', 'Riviera', and 'Barbados', and increased in 'Contessa'. During Spring 2006 (March–May) WSC decreased sharply in 'Barbados', 'Contessa', and 'Yukon', but increased in 'NuMex Sahara'. WSC in all other bermudagrass cultivars remained constant from Mar. to May 2006 (Fig. 2). During early summer (May–July 2006), WSC also increased in 'Princess 77', 'Riviera', 'Barbados', 'Contessa', and 'Yukon', and all cultivars tested had accumulated equal amounts of WSC in their stolons (Fig. 2). The high content of WSC observed in most species in November can be attributed to a reduction in grass growth that is accompanied by an accumulation of carbohydrates when the plants' metabolism is still active. These findings support those of Dunn and Nelson (1974) and Trenholm et al. (1998) who found increased fall levels of total carbohydrates and sucrose in 'Midway' and 'U3' bermudagrass cultivars (Dunn and Nelson, 1974) and of TNC in 'FloraDwarf' bermudagrass (Trenholm et al., 1998). Zhang et al. (2006) also reported TNC accumulation in 'Riviera' and 'Princess 77' bermudagrasses after cold acclimation. Similarly, the depletion of carbohydrates during early spring is associated with the utilization of carbohydrate as an energy source to

Fig. 1. Stolon dry weight of nine bermudagrass cultivars as affected by sampling date. Data points represent an average of four replicates. Error bar in the top left corner of the graph shows Fisher's protected least significant difference at $\alpha = 0.05$ (LSD) and can be used to determine significant differences between grasses and sampling dates; 1 g·m⁻² = 0.0033 oz/ft².

support spring green-up and growth (Rogers et al., 1975). The increase of carbohydrate content observed in early summer can be attributed to photosynthesis in new leaves (Fig. 2). Differences in WSC among bermudagrass cultivars occurred at the end of the winter months, with 'Yukon' exhibiting the highest values in March coinciding with highest stolon dry weight in 'Yukon' and 'Contessa'. Dunn and Nelson (1974) also reported differences in fall and winter stolon dry weight between bermudagrass cultivars and concluded better winter survival for cultivars with higher stolon weight. In March, carbohydrate concentration in 'Yukon' was more than double than

that of 'La Paloma', 'Mohawk', 'NuMex Sahara', 'Princess 77', 'Riviera', 'SR 9554', and 'Barbados'. 'La Paloma' and 'NuMex Sahara' depleted their carbohydrate reserves to their lowest levels in March, while 'Barbados', 'Contessa', and 'Yukon' exhibited lowest WSC content in May.

SPRING GREEN-UP. 'Yukon' (group 1) showed earliest green-up (Fig. 3) and reached 80% green cover by end of April (Table 2). 'Mohawk', 'La Paloma', 'NuMex Sahara', 'SR 9554', 'Barbados', and 'Contessa' reached 80% green cover by mid-May (Table 2). Last, 'Riviera' and 'Princess 77' showed the slowest greening (Fig. 3) and needed over 40 d longer to reach 80% green cover than Yukon (Table 2). These spring green-up results are in part confirmed by the National Turfgrass Evaluation Program's (NTEP) 2002 bermudagrass trial (NTEP, 2009). From a total of 20 test locations across the continental United States, three reported that 'Yukon' was the earliest to achieve green-up, followed by 'Riviera' and then 'Princess 77' during spring after establishment. However, in this trial there was no difference in green-up between 'Riviera' and 'Princess 77'. These results, equal green-up after establishment between 'Riviera' and 'Princess 77', have been reported by three locations in the NTEP trial (NTEP, 2009).

PREDICTING GREEN-UP FROM STOLON DRY WEIGHT AND WSC. The regression analysis revealed that neither November ($P = 0.735$) nor March ($P = 0.414$) stolon dry weight values were significant predictors of D80. However, November ($P = 0.018$) and March ($P = 0.002$) WSC values were significant predictors of D80 with regression coefficients of 0.57 and 0.77, respectively. These results demonstrate the equal importance of fall and spring WSC for early spring green-up in bermudagrass after establishment, and show that cultivars with highest WSC concentrations in fall and spring recovered more rapidly from dormancy than those with low concentrations.

Conclusion

These results demonstrate that bermudagrasses with the highest winter concentrations of WSC in stolons showed the earliest spring green-up.

Thus, to achieve short dormancy periods and rapid spring green-up, cultivars need to be developed that promote storage and maintenance of large amounts of WSC until the end of winter. Furthermore, fall fertilization and other maintenance strategies that promote WSC storage during hardening-off periods and that help maintain high levels until the end of winter should be developed. More research is needed to determine the effect of different climatic conditions on WSC storage and early spring green-up. These results also demonstrate the need for additional longer-term research on the importance of WSC in early spring green-up of bermudagrass. Our study focused on WSC in stolons in the first year of establishment, but further research is needed to determine if fall WSC concentrations in stolons and rhizomes of mature grasses have a similar effect on spring green-up.
