## ABSTRACT

We present high-precision multiband photometry for the globular cluster (GC) M2. We combine the analysis of the photometric data obtained from the *Hubble Space Telescope* UV Legacy Survey of Galactic GCs GO-13297, with chemical abundances by Yong et al., and compare the photometry with models in order to analyse the multiple stellar sequences we identified in the colour–magnitude diagram. We find three main stellar components, composed of metal-poor, metal-intermediate, and metal-rich stars (hereafter referred to as population A, B, and C, respectively). The components A and B include stars with different *s*-process element abundances. They host six sub-populations with different light-element abundances, and exhibit an internal variation in helium up to  $\Delta Y \sim 0.07$  dex. In contrast with M22, another cluster characterized by the presence of populations with different metallicities, M2 contains a third stellar component, C, which shows neither evidence for sub-populations nor an internal spread in light-elements. Population C does not exhibit the typical photometric signatures that are associated with abundance variations of light elements produced by hydrogen burning at hot temperatures. We compare M2 with other GCs with intrinsic heavy-element variations and conclude that M2 resembles M22, but it includes an additional stellar component that makes it more similar to the central region of the Sagittarius galaxy, which hosts a GC (M54) and the nucleus of the Sagittarius galaxy itself.

**Key words:** stars: abundances – Hertzsprung–Russell and colour–magnitude diagrams – globular clusters: general – globular clusters: individual: M2, M22, NGC1851, Omega Centauri, M54, Terzan 5.

## 1 INTRODUCTION

The *Hubble Space Telescope* (*HST*) ‘Legacy Survey of Galactic Globular Clusters: Shedding UV Light on Their Populations and Formation’ is designed to image 47 Galactic Globular Clusters (GCs) through the filters *F275W*, *I336W* and *F438W* of the

\*Based on observations with the NASA/ESA *Hubble Space Telescope*, obtained at the Space Telescope Science Institute, which is operated by AURA, Inc., under NASA contract NAS 5-26555.

†E-mail: [antonino.milone@anu.edu.au](mailto:antonino.milone@anu.edu.au)

ultraviolet and visual channel (UVIS) of the Wide Field Camera 3 (WFC3) on board of *HST* (GO-13297, PI. G. Piotto; see Piotto et al. 2014 – Paper I hereafter – for details). GO-13297 will complement the *F606W* and *F814W* data base from the Advanced Camera for Survey (ACS) GC Treasury programme (GO-10775, PI. A. Sarajedini, see Sarajedini et al. 2007) to provide homogeneous and accurate photometry of GCs in five bands, from  $\sim 275$  to  $\sim 814$  nm. The main goal of this project is to detect and characterize multiple stellar populations in GCs. Indeed, these five filters have shown a high sensitivity to abundance variations including light-element and helium (see Milone et al. 2012a; Milone et al. 2013 and Paper I for details).

In this paper, we focus on NGC 7089 (M2), which is one of the few GCs that exhibits a split sub giant branch (SGB) in the visual colour–magnitude diagram (CMD, see the  $m_{F606W}$  versus  $m_{F606W} - m_{F814W}$  CMD in Piotto et al. 2012). The  $U$  versus  $U - V$  CMD of M2 shows a poorly-populated red giant branch (RGB) on the redward side of the main RGB (Grundahl 1999; Lardo et al. 2012). Spectroscopy has revealed that stars in the two RGBs have different abundances in terms of their overall metallicity (Yong et al. 2014, hereafter Y14) and in terms of their  $s$ -process elements, with the red-RGB being also  $s$ -rich (Lardo et al. 2013; Y14). More specifically, Y14 have shown that the metallicity distribution of M2 stars has three peaks, around  $[\text{Fe}/\text{H}] \sim -1.7, -1.5, \text{ and } -1.0$ . Therefore M2 also is one of the very few Galactic GCs with a large intrinsic difference in iron abundance ( $\Delta[\text{Fe}/\text{H}] \gtrsim 0.1$  dex), where Supernovae (SNe) have likely played a major role in the internal chemical-enrichment history.<sup>1</sup> The other presently known members of this short list are:  $\omega$  Centauri, M22, Terzan 5, M54, and NGC 5824 (e.g. Norris & Da Costa 1995; Da Costa et al. 2009; Ferraro et al. 2009; Marino et al. 2009, Carretta et al. 2010a,b; Johnson & Pilachowski 2010; Marino et al. 2011a,b; Da Costa, Held & Saviane 2014). NGC 1851 is an intriguing candidate as it exhibits two main stellar populations with distinct  $s$ -element abundance and a difference in  $[\text{Fe}/\text{H}]$  of  $\sim 0.05$  dex (Yong & Grundahl 2008; Carretta et al. 2010c; Gratton et al. 2012; Marino et al. 2014). Following Marino et al. (2012), we will refer to these non-mono-metallicity GCs as ‘anomalous’. This paper describes the stellar population properties of one of these anomalous GCs: M2. We combine high-precision multiwavelength photometry from GO-13297 and GO-10775 with information from high-resolution spectroscopy to investigate multiple stellar populations in M2 and understand their formation and evolution. This paper is organized as follows: in Section 2, we describe the data and the reduction procedures. The  $m_{F275W}$  versus  $m_{F275W} - m_{F814W}$  CMD of M2 is discussed in Section 3, while in Section 4 and Section 5, we identify the stellar populations along the RGB and the main sequence (MS), respectively, and infer their abundance of iron and light elements. We estimate the age and the helium content of multiple stellar populations in Section 6 and compare M2 with other anomalous GCs in Section 7. Summary and conclusions are given in Section 8.

## 2 DATA AND DATA ANALYSIS

In order to investigate multiple stellar populations in M2, we have used images taken with ACS/WFC and WFC3/UVIS on board the *HST*. The ACS/WFC data set consists of  $5 \times 340$  s long exposures

<sup>1</sup> Small star-to-star iron variations, at the level of  $\lesssim 0.05$  dex are likely present in most GCs and can be detected from high-precision spectroscopic measurement (Yong et al. 2013).

in *F606W* and *F814W* plus one 20 s short exposure taken through each of the same filters. These images were taken on 2006 April 16 as part of the ACS *HST* Treasury Survey of GCs (GO 10775, PI. A. Sarajedini). The astro-photometric catalogue of stars in the ACS/WFC field used in this paper has been published by Anderson et al. (2008).

The WFC3/UVIS data set includes  $6 \times \sim 700$  s exposures in *F275W*,  $6 \times \sim 300$  s in *F336W*, and  $3 \times \sim 60$  s in *F438W*. These images were taken on 2013 August 14, 29, and October 18 as part of GO-13297. These data were corrected for charge transfer deficiencies by using an algorithm that was developed specifically for UVIS and is based on the method and the software of Anderson & Bedin (2010). The reduction has been performed with `IMG2XYM_WFC3`, software developed by Bellini et al. (2010) mostly based on `IMG2XYM_WFI` (Anderson et al. 2006). Photometry and astrometry have been independently carried out for each exposure by using a set of spatially-variable empirical point spread functions (PSFs). We have corrected the stellar positions for geometrical distortion by using the solution from Bellini & Bedin (2009) and Bellini, Anderson & Bedin (2011) and have calibrated the photometry into the VEGA-mag flight system as in Bedin et al. (2005). Stellar proper motions have been obtained as in Anderson & King (2003) by comparing the average stellar positions measured from GO-10775 and from GO-13297 data. Our data cover a temporal baseline of 7.5 yr. Since the cluster has been centred in both the ACS/WFC and WFC3/UVIS fields of view, five-band photometry and proper motions are available for stars in an  $\sim 2.7$  arcmin  $\times$   $2.7$  arcmin region around the centre of M2.

As the photometric separation among sequences populated by different stellar populations is typically small, the study of multiple populations along the CMD of any GC requires very accurate photometry. Because of this, we have selected the best-measured stars in our sample, by following the same selection criteria as described in Milone et al. (2009), which are based on several diagnostics, including the amount of scattered light from neighbouring stars, PSF-fit residuals, and rms scatter in position measurements. Photometry has been corrected for differential reddening by using the method explained in detail in Milone et al. (2012a). Briefly, we identified for each star the 55 nearest well-measured MS stars and determined the colour distance from the MS ridge line along the reddening direction. The median colour distance of the 55 neighbours has been assumed as the best estimate of differential reddening for each target star, and has been applied as a correction to its colour. The reddening in the direction of NGC 7089 is  $E(B - V) \sim 0.06$  mag (Harris 1996 updated as in 2010, see also section 6). We have found that reddening variations in the analysed field of view are, on average,  $\Delta E(B - V) \sim 0.007$  mag and never exceed 0.021 mag.

## 3 THE $F275W$ VERSUS $F275W - F814W$ CMD

The left-hand panel of Fig. 1 shows the complete  $m_{F275W}$  versus  $m_{F275W} - m_{F814W}$  CMD of M2 members (black dots), and field stars (grey crosses), selected on the basis of their proper motions. The vector-point diagram (VPD) of proper motions in WFC3/UVIS pixel units per year is plotted in the inset and includes all the stars plotted in the CMD. Since we have used M2 members as reference stars to calculate proper motions, the bulk of stars around the origin of the VPD is mostly made of clusters members while field stars have larger proper motions. We have thus drawn a red circle to separate the probable cluster members from field stars. In this paper, we analyse cluster members only. To identify them, we have chosen a radius of  $0.03$  pixel  $\text{yr}^{-1}$  that corresponds to five times the average

**Figure 1.** Left-hand panel:  $m_{F275W}$  versus  $m_{F275W} - m_{F814W}$  CMD of stars in the WFC3/UVIS field of view centred on M2. Cluster members and field stars, selected on the basis of their proper motions, are represented with black dots, and grey crosses, respectively. The VPD of proper motions is plotted in the inset and the stars within the red circle are considered as cluster members. A zoom-in of the same CMD around the SGB is plotted in the upper-right panel. Lower-right panel:  $[Y/Fe]$  versus  $[Fe/H]$  for RGB stars from Y14. Metal-poor, metal-intermediate, and metal-rich stars are represented as black circles, red triangles, and aqua stars, respectively. In the left-hand panel, we used the same symbols to highlight the Y14 stars we could cross-identify in our photometric catalogue.

proper-motion dispersion along the  $X$  and  $Y$  direction for the bulk of stars around the origin of the VPD. There are 47 candidate-field stars with proper motions larger than  $0.03 \text{ pixel yr}^{-1}$ . This sample likely includes also cluster stars with large proper motions indeed, from the Galactic model by Girardi et al. (2005) we expect less than 20 field stars in a  $2.7 \text{ arcmin} \times 2.7 \text{ arcmin}$  region in the direction of M2.

The CMD of Fig. 1 reveals that M2 hosts a complex multiple-sequence pattern, with a multiplicity of RGBs and SGBs and a multimodal horizontal branch (HB). The most surprising feature is a poorly-populated sequence, which runs on the red side of the majority of the stars in M2 and can be followed continuously from the lower part of the MS to the SGB, up to the RGB tip. The wide separation from the bulk of M2 stars is an unusual feature, as multiple MSs and RGBs in ‘normal’ GCs usually merge around the SGB. Furthermore, in GCs, the colour separation between multiple MSs typically increases when moving from the MS turn-off towards fainter magnitudes, in contrast with what is observed for the tiny reddest MS in M2.

An additional, sparsely-populated, SGB is clearly visible, between the main SGB and the faintest SGB. The three SGBs are more clearly seen in the upper-right panel of Fig. 1, which is a zoom of the left-hand panel CMD around the SGB.

In order to explore the origin of the multiple sequences observed on the  $m_{F275W}$  versus  $m_{F275W} - m_{F814W}$  CMD, we took advantage of the high-resolution spectroscopic data recently pub-

lished by Y14. This study shows that red giants in M2 exhibit a multimodal abundance distribution for iron and for those neutron-capture elements that are associated with  $s$ -processes in Solar system material. Specifically there is a large metallicity variation, with three groups of metal-poor ( $[Fe/H] = \sim -1.7$ ), metal-intermediate ( $[Fe/H] = \sim -1.5$ ), and metal-rich ( $[Fe/H] = \sim -1.0$ ) stars. Metal-intermediate stars are also enhanced in Yttrium and Zirconium by  $\sim 0.5$  dex with respect to the remaining stars of M2.

The lower-right panel of Fig. 1 shows  $[Y/Fe]$  versus  $[Fe/H]$  from Y14, with black, red, and aqua symbols representing their metal-poor, metal-intermediate, and metal-rich stars, respectively. The 10 stars for which *HST*  $F275W$  and  $F814W$  photometry is available are superimposed on the  $m_{F275W}$  versus  $m_{F275W} - m_{F814W}$  CMD. The three metallicity groups populate different RGBs: the bright, the middle, and the faint RGB correspond to metal-poor, metal-intermediate, and metal-rich populations of Y14, respectively.

#### 4 MULTIPLE POPULATIONS ALONG THE RGB

A number of recent studies (see Paper I and references therein) have shown that the RGB, SGB, and the MS of GCs can often be separated into distinct sequences of stars, and that appropriate combinations of  $F275W$ ,  $F336W$ ,  $F438W$ , and  $F814W$  magnitudes are powerful tools for identifying these multiple populations.

The efficiency of these filters in separating different stellar populations is closely connected to the chemical properties of GC

**Figure 2.** Left:  $m_{F438W}$  versus  $m_{F336W} - m_{F438W}$  CMD (left-hand panel); Right:  $m_{F814W}$  versus  $C_{F275W, F336W, F438W}$  diagram for M2 stars. AGB, HB, and BSSs, selected by eye, have been marked with red crosses, green dots, and blue circles, respectively.

sub-populations. The fact that the  $F275W$  filter includes the OH molecular band,  $F336W$  the NH band, and  $F438W$  the CH and CN bands make them very sensitive to the effect of molecular bands in the stellar atmosphere, hence on the degree of CNO processing of the various sub-populations. First-generation stars are enhanced in carbon and oxygen, have low nitrogen content, and are relatively faint in  $F275W$  and  $F438W$ , and bright in  $F336W$ . Conversely, second-generation stars, which are carbon/oxygen poor and nitrogen rich, are relatively bright in  $F275W$  and  $F438W$  and faint in  $F336W$ . The result is that first-generation stars have bluer  $m_{F336W} - m_{F438W}$  colours than second-generation stars at the same luminosity (Marino et al. 2008; Bellini et al. 2010; Sbordone et al. 2011; Milone et al. 2012b), while, for the same stars, the  $m_{F275W} - m_{F336W}$  colour order is reversed. As a consequence, the  $C_{F275W, F336W, F438W} = (m_{F275W} - m_{F336W}) - (m_{F336W} - m_{F438W})$  pseudo-colour defined by Milone et al. (2013) is an extremely powerful and valuable tool to maximize the separation among the various sub-populations.

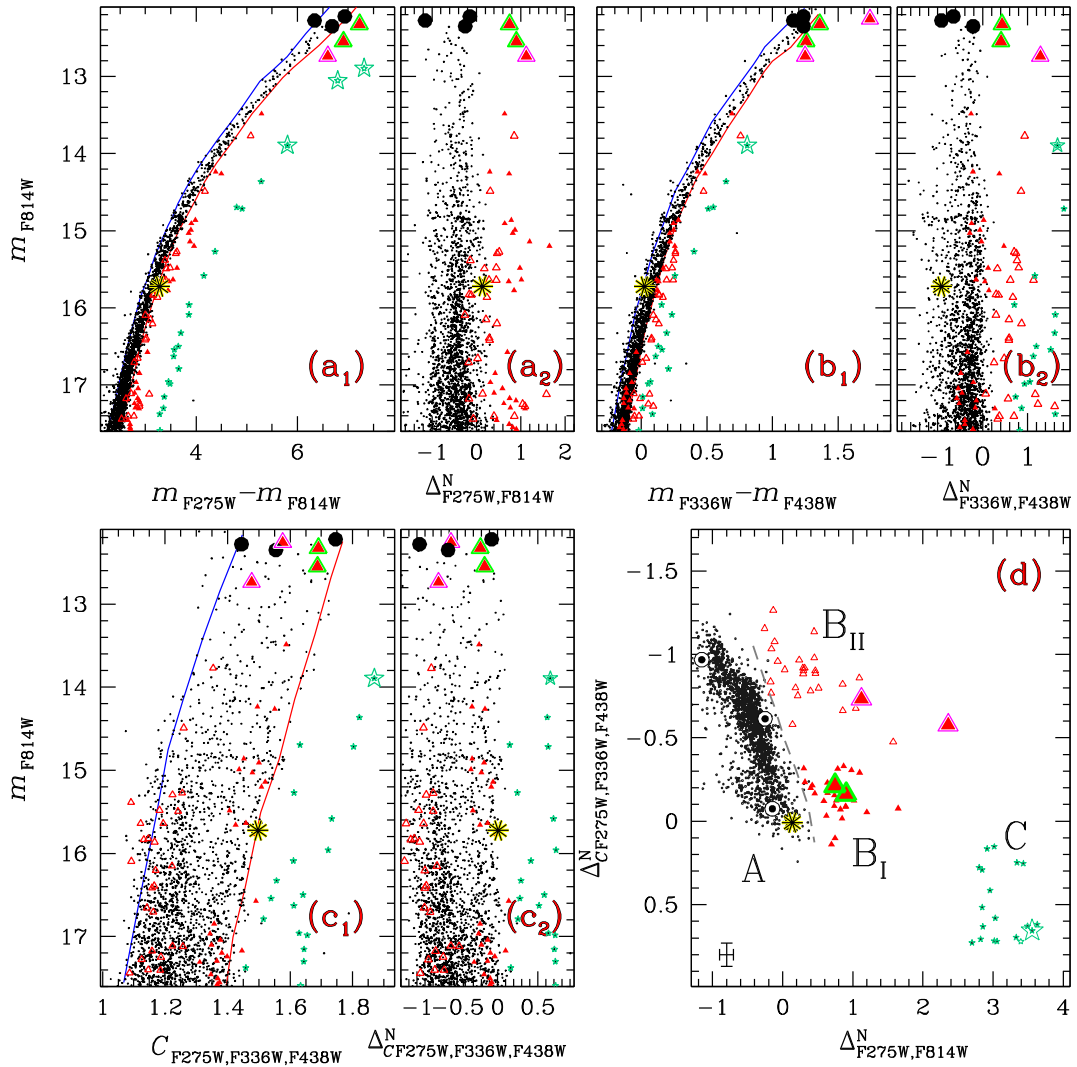

Fig. 2 shows the  $m_{F438W}$  versus  $m_{F336W} - m_{F438W}$  CMD and the  $m_{F814W}$  versus  $C_{F275W, F336W, F438W}$  diagram of proper-motion-selected M2 members. We have marked stars that, on the basis of their position in the left-hand panel CMD, are likely HB and asymptotic-giant branch (AGB) stars with green dots and red crosses, while blue stragglers (BSSs), have been selected from the right-hand panel diagram and have been represented with blue circles. A visual inspection of the latter diagram reveals that the RGB of M2, which shows at most a small colour dispersion using  $m_{F336W} - m_{F438W}$  colour, spans a wide range in  $C_{F275W, F336W, F438W}$ , with distinct RGBs. AGB stars are also distributed over a wide interval of  $C_{F275W, F336W, F438W}$ , in close analogy with what is observed for the RGB, suggesting that the AGB of M2 also hosts multiple stellar populations.

Multiple populations are also characterized by different helium content. Typically, second-generation stars are enhanced in helium and are hotter than first-generation stars at the same luminosity. The

$m_{F275W} - m_{F814W}$  colour is quite sensitive to the oxygen abundance of the stellar populations through the OH molecule. In addition, the wide colour baseline provided by  $F275W$  and  $F814W$  is very sensitive to the effective temperatures of stars, thus providing a valuable tool to identify stellar populations with different helium content or metallicity (see Milone et al. 2012b, for details).

To further investigate stellar populations along the RGB of M2, we combined information from three distinct diagrams: (i)  $m_{F814W}$  versus  $m_{F275W} - m_{F814W}$ , (ii)  $m_{F814W}$  versus  $C_{F275W, F336W, F438W}$ , (iii)  $m_{F814W}$  versus  $m_{F336W} - m_{F438W}$ . We show these three CMDs in the panels (a<sub>1</sub>), (b<sub>1</sub>), and (c<sub>1</sub>) of Fig. 3, respectively. In the rest of this section, we have excluded AGB and HB stars, and restricted our analysis to RGB stars with  $12.1 < m_{F814W} < 17.6$ . We started by deriving by hand the blue and the red fiducial lines that are shown in panels (a<sub>1</sub>), (b<sub>1</sub>), and (c<sub>1</sub>) of Fig. 3 and mark the blue and the red envelope of the main RGB. The fiducials are then used to rectify the RGB in such a way that the blue and the red fiducials translate into vertical lines with abscissa equal to  $-1$  and  $0$ , respectively. The abscissa in panels (a<sub>2</sub>), (b<sub>2</sub>), and (c<sub>2</sub>) of Fig. 3 are named  $\Delta_{F275W, F814W}^N$ ,  $\Delta_{F336W, F438W}^N$ , and  $\Delta_{CF275W, F336W, F438W}^N$ , respectively, and have been calculated for each star as:  $\Delta_X^N = [(X - X_{\text{bluefiducial}})/(X_{\text{redfiducial}} - X_{\text{bluefiducial}})] - 1$  where  $X = (m_{F275W} - m_{F814W})$ ,  $(m_{F336W} - m_{F438W})$ , or  $C_{F275W, F336W, F438W}$ .

Panel (d) of Fig. 3 shows  $\Delta_{CF275W, F336W, F438W}^N$  as a function of  $\Delta_{F275W, F814W}^N$ . In this section, we exploit this diagram to identify the three main stellar components of M2 (A, B, and C) and the two sub-populations of the component B (namely  $B_I$ , and  $B_{II}$ ) along the RGB. Most of the stars, including those of the most metal-poor metallicity peak detected by Y14, are distributed in the left-hand region of the diagram and follow a well-defined pattern. In this paper, we will refer to these stars as population A and represent them with black symbols. Noticeably, a small fraction of RGB stars in M2 exhibit large values of  $\Delta_{F275W, F814W}^N$  and  $\Delta_{CF275W, F336W, F438W}^N$  and are separated from RGB-A stars by the dashed line that we have

**Figure 3.** Zoom-in of the  $m_{F814W}$  versus  $m_{F275W} - m_{F814W}$  (panel a<sub>1</sub>),  $m_{F814W}$  versus  $m_{F336W} - m_{F438W}$  CMD (panel b<sub>1</sub>), and versus  $C_{F275W, F336W, F438W}$  diagrams around the RGB. The two fiducials used to verticalize the RGB are shown as thick red and blue lines (see text for details). The verticalized diagrams are plotted in panels (a<sub>2</sub>), (b<sub>2</sub>), and (c<sub>2</sub>). Large black dots, red triangles, and aqua stars, respectively, mark the metal-poor, metal-intermediate, and metal-rich stars observed by Y14. Panel (d) shows the  $\Delta_{CF275W, F336W, F438W}^N$  versus  $\Delta_{F275W, F814W}^N$  diagram for RGB stars. RGB-A, RGB-B, and RGB-C stars are coloured black, red, and aqua, respectively. The mean error bar is shown in the lower-left corner. The magenta and green large triangles mark the metal-intermediate/Na-rich stars and metal-intermediate/Na-poor stars, respectively. The star analysed by Lardo et al. (2012) has been represented with a large asterisk.

drawn by hand. We have arbitrarily divided stars on the right of this line into two samples: (i) a group of stars with  $\Delta_{F275W, F814W}^N > 2.5$ , which we have represented with aqua symbols and named population C, and (ii) another group with intermediate  $\Delta_{F275W, F814W}^N$  values, marked with red triangles and named population B. These colours and symbols are used consistently in the other panels of this figure.

Because of their colours, stars on RGB-C correspond to the reddest RGB discussed in Section 3 and include the only metal-rich spectroscopic targets for which  $F275W$ ,  $F336W$ ,  $F438W$ , and  $F814W$  photometry is available.

RGB-B has bluer  $m_{F275W} - m_{F814W}$  and  $m_{F336W} - m_{F438W}$  colours with respect than the RGB-C, but it is redder than the RGB-A. RGB-B stars span a wide  $m_{F275W} - m_{F814W}$  and  $m_{F336W} - m_{F438W}$  colour range and appear to cluster around two different regions in the  $\Delta_{CF275W, F336W, F438W}^N$  versus  $\Delta_{F275W, F814W}^N$  plane, indicating the existence of at least two stellar populations within group B. We name them populations B<sub>I</sub> and B<sub>II</sub> as illustrated in Fig. 3. The four

metal-intermediate targets studied by Y14 for which photometry is available belong to the RGB-B group. Among them, two stars are highly enhanced in sodium ( $[Na/Fe] \sim 0.55$ ) and the other two have lower sodium abundance ( $[Na/Fe] \sim 0.15$ ). Na-rich and Na-poor stars, marked as magenta and large green triangles the panel (d) of Fig. 3 occupy the B<sub>I</sub> and B<sub>II</sub> regions in the  $\Delta_{CF275W, F336W, F438W}^N$  versus  $\Delta_{F275W, F814W}^N$  diagram, respectively. This fact confirms that these star groups represent different stellar sub-populations that have different sodium abundance.

Lardo et al. (2012) have performed a CN- and CH-index study of 38 red giants of M2 and have identified two groups of CN-strong (CH-weak) and CN-weak (CH-strong) stars. Furthermore, they have determined the abundance of carbon and nitrogen in 35 stars and found significant star-to-star variations of both elements at all the luminosities that form an extended C–N anticorrelation. *HST* photometry is available for only one star (#6609) analysed by Lardo and collaborators. It is CN weak (Lardo et al. 2012), belongs to population A, and has been represented with a black large asterisk

**Figure 4.** Upper-left panel:  $\Delta_{F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  Hess diagram for stars in the RGB-A. The reference frame adopted to measure the polar angle,  $\theta$ , for RGB-A stars is also represented. The long- and short-notched lines mark different angles, from  $\theta = 0^\circ$  to  $360^\circ$  in steps of  $90^\circ$ , and  $45^\circ$ , respectively. See text for details. Upper-right panel: histogram distribution of  $\theta$  for RGB-A stars. The least-squares best-fitting multi-Gaussian function is represented with grey line, while its four components are coloured black, green, magenta, and cyan. Lower panels:  $\Delta_{F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  diagram for RGB-A stars (left-hand panel). Stars observed by Y14 are represented with large symbols. We have defined four groups of stars ( $A_I$ – $A_{IV}$ ), and coloured them black, green, magenta, and cyan, respectively. The same stars are plotted with the same colour codes in the  $\Delta_{CF275W,F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  diagram shown in the lower-right panel. The filled and open red triangles represent RGB-BI and RGB-BII stars, respectively. The mean error bar is plotted in the lower-left corner of each panel.

in Fig. 3. Unfortunately, Lardo et al. (2012) have not inferred C and N abundances for this star because of the low signal-to-noise ratio of their spectra.

From the number of stars in the different groups of panel (d) of Fig. 3, we infer that in the central region of M2 96.1  $\pm$  2.2 per cent of stars belong to population A, 2.9  $\pm$  0.4 per cent to population B, and 1.0  $\pm$  0.2 per cent to population C. Populations  $B_I$  and  $B_{II}$ , contain approximately the same number of stars (48  $\pm$  12 and 52  $\pm$  12 per cent of RGB-B stars, respectively).

The upper-left panel of Fig. 4 shows the Hess diagram in the  $\Delta_{F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  plane. Here RGB-A stars exhibit an even more complex pattern, defining a kind of semicircle.

About half of the stars are clustered around ( $\Delta_{F275W,F814W}^N, \Delta_{F336W,F438W}^N$ )  $\simeq$  (−0.5, −0.2). The presence of three additional clumps suggest that the RGB-A hosts four stellar sub-populations and we use the diagram plotted in the lower-left panel to define them. To do this, we have somewhat

arbitrarily separated four groups of stars in the  $\Delta_{F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  diagram and we have named them  $A_I$ ,  $A_{II}$ ,  $A_{III}$ , and  $A_{IV}$ , and coloured them in black, green, magenta, and cyan, respectively. The same colours are used consistently in the  $\Delta_{CF275W,F336W,F438W}^N$  versus  $\Delta_{F275W,F814W}^N$  diagram plotted in the lower-right panel.

In order to estimate the fraction of stars in each sub-population, we have introduced the polar reference frame shown in the upper-left panel of Fig. 4. To do this, we have arbitrarily translated the origin to the point indicated by the red circle ( $\Delta_{F275W,F814W}^N, \Delta_{F336W,F438W}^N$ ) = (−0.55, −0.7) and rotated the axes by  $208^\circ$  counterclockwise. The histogram distribution of the polar angle,  $\theta$ , in the upper-right panel clearly shows four main peaks. We have fitted this distribution with a least-squares fit of the sum of four Gaussians and estimated the fraction of stars in each component from the area of the four Gaussians. We infer that 8  $\pm$  3, 23  $\pm$  4, 51  $\pm$  5, and 18  $\pm$  4 per cent of stars belong to populations  $A_I$ – $A_{IV}$ , respectively.

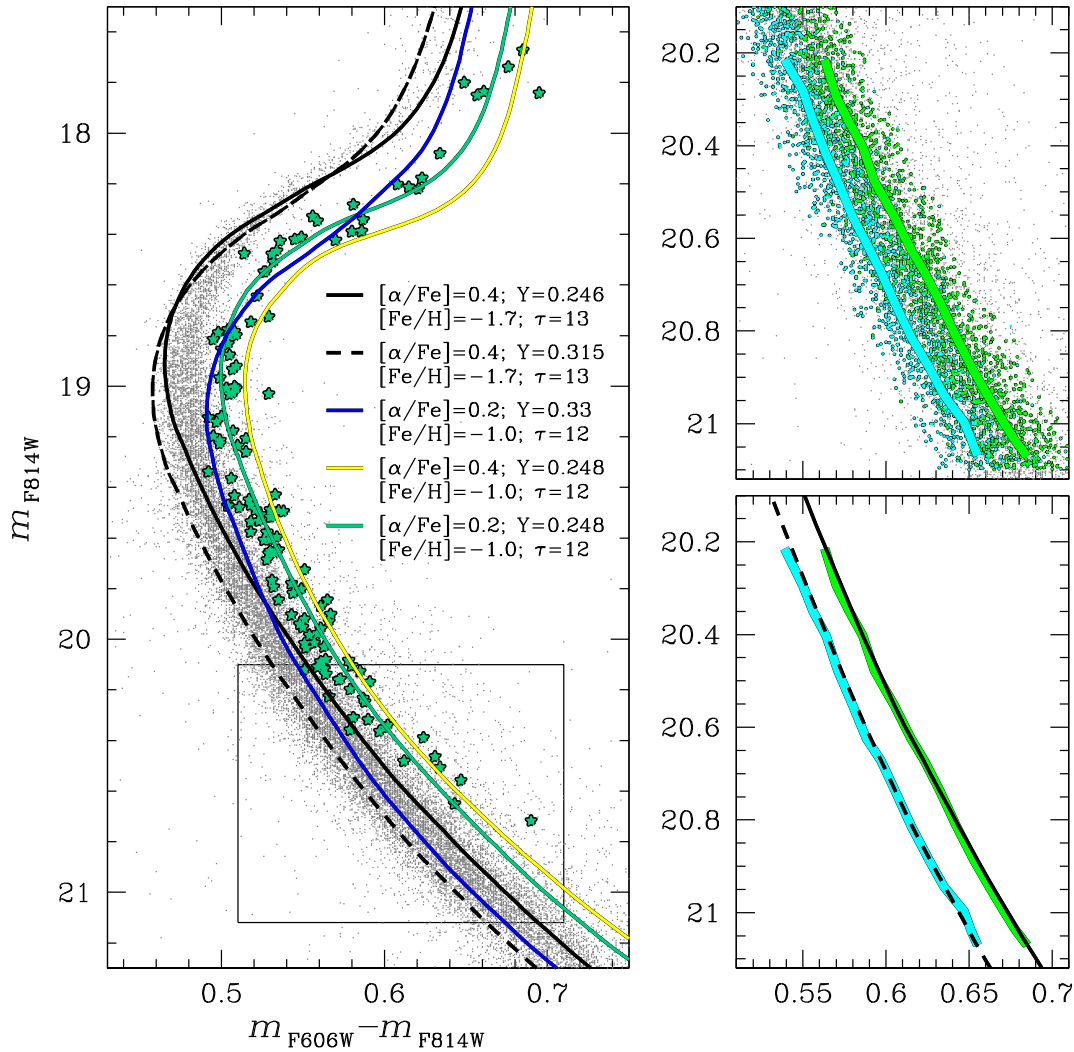

**Figure 5.** Upper panels:  $m_{F814W}$  versus  $m_{F275W} - m_{F814W}$  (left),  $m_{F814W}$  versus  $C_{F275W, F336W, F438W}$  (right) diagrams of MS stars. The insets show  $m_{F814W}$  against  $\Delta_{F275W, F814W}^N$  and  $m_{F814W}$  against  $\Delta_{C_{F275W, F336W, F438W}}^N$  for stars with  $20.05 < m_{F814W} < 21.10$ , and the corresponding histogram distribution. The  $\Delta_{F275W, F814W}^N$  and  $\Delta_{C_{F275W, F336W, F438W}}^N$  have been obtained by subtracting to each star the colour of the fiducial line drawn by hand to reproduce the CMD. Lower-left panel:  $\Delta_{C_{F275W, F336W, F438W}}^N$  versus  $\Delta_{F275W, F814W}^N$  Hess diagram. In the right-hand panel, we have coloured green and cyan the stars we consider to be the progeny of group  $A_{II}$  and  $A_{IV}$  identified along the RGB.

The nature of these different stellar populations on RGB-A can be clarified by again combining our photometric results, with the chemical abundances from the spectroscopy in Y14. The green, magenta, and cyan circles superimposed on the diagram of Fig. 4 refer to sodium-poor stars ( $[Na/Fe] = -0.16 \pm 0.13$ ), sodium-intermediate ( $[Na/Fe] = 0.18 \pm 0.13$ ), and sodium-rich ( $[Na/Fe] = 0.35 \pm 0.13$ ) in Y14, respectively. The star marked by the black asterisk is CN weak (Lardo et al. 2012) and belongs to population  $A_{II}$ . The fact that populations  $A_{II}$  and  $A_{III}$  host the Na-poor and the Na-intermediate stars, respectively, suggests that these two stellar populations host stars with different light-element abundances. The most Na-rich star of Y14 is not clearly associated with any bump of stars, although it is possible that it might be related to population  $A_{IV}$ , at least for the  $\Delta_{C_{F275W, F336W, F438W}}^N$  value. Its anomalous position in the  $\Delta_{F275W, F814W}^N$  and  $\Delta_{F336W, F438W}^N$  diagrams may be intrinsic, but we cannot exclude the possibility that it is due to photometric errors.

## 5 MULTIPLE POPULATIONS ALONG THE MS

In Section 3, we have shown that M2 includes a poorly-populated sequence of stars that is associated with population C (hereafter MS-C) and is clearly visible in the CMD of Fig. 1 on the redward side of the main MS. We postpone the analysis of MS-C to the next section and analyse in this section the bulk of MS stars which are mostly associated with population A (MS-A). It is not possible to identify population-B stars along the MS from our data set.

In order to identify possible multiple stellar populations along MS-A of M2, we followed the same approach adopted in Section 4 for the RGB. The  $m_{F814W}$  versus  $m_{F275W} - m_{F814W}$  Hess diagram for MS stars is shown in the left-hand panel of Fig. 5. Below  $m_{F814W} \sim 20$ , the MS of M2 is widely spread in colour with a tail of stars on the blue side of the bulk of MS stars. The colour separation between the red and the blue sides of MS-A is about 0.2 mag at  $m_{F814W} \sim 20$  and increases towards fainter magnitudes, reaching  $\sim 0.5$  mag at  $m_{F814W} \sim 21$ . It is significantly larger

**Figure 6.** Left:  $m_{F814W}$  versus  $m_{F606W} - m_{F814W}$  CMD of M2, with five superimposed isochrones with the values of  $[Fe/H]$ ,  $[\alpha/Fe]$ , age, and  $Y$  listed in the figure inset. Aqua symbols highlight population C stars. Right: zoom-in of the same CMD shown in the left-hand panel around the MS (upper panel).  $A_{II}$  and  $A_{IV}$  stars, as defined in Fig. 5, are plotted with green and cyan points, respectively. The green and the cyan line are the fiducials of  $A_{II}$  and  $A_{IV}$  MSs. In the lower-right panel, we have superimposed the two metal-poor isochrones on the fiducials.

than the  $m_{F275W} - m_{F814W}$  colour error, which is between 0.03 and 0.08 mag in the same magnitude interval.<sup>2</sup> The verticalized  $m_{F814W}$  versus  $\Delta_{F275W, F814W}^N$  is plotted in the inset for stars with  $20.05 < m_{F814W} < 21.1$ . Here, the MS-A spread is more clearly visible. The histogram distribution of  $\Delta_{F275W, F814W}^N$  is skewed towards the blue, further confirming the presence of a blue tail of stars.

The  $m_{F814W}$  versus  $C_{F275W, F336W, F438W}$  Hess diagram of MS stars in the upper-right panel of Fig. 5 furthermore reveals a red tail of stars, confirmed by the  $m_{F814W}$  versus  $\Delta_{C_{F275W, F336W, F438W}}^N$  verticalized diagram and the histogram of the  $\Delta_{C_{F275W, F336W, F438W}}^N$  distribution shown in the inset. In the lower-left panel, we plot  $\Delta_{C_{F275W, F336W, F438W}}^N$  as a function of  $\Delta_{F275W, F814W}^N$  for MS-A stars with  $20.05 < m_{F814W} < 21.10$ . The comparison of this figure with the corresponding plot shown in the lower-right panel of Fig. 4 for the

RGB reveals that MS-A stars and the RGB-A share similarities. In both cases, there is a tail of stars with small  $\Delta_{F275W, F814W}^N$  and  $\Delta_{C_{F275W, F336W, F438W}}^N$  and second one with large  $\Delta_{F275W, F814W}^N$  and  $\Delta_{C_{F275W, F336W, F438W}}^N$ .

To further investigate multiple populations along the MS-A, we selected by eye two groups of stars with extreme  $m_{F275W} - m_{F814W}$  and  $C_{F275W, F336W, F438W}$  and highlighted them in the lower-right panel of Fig. 5 with cyan and green colours, respectively. To minimize the effect of binaries or stars with large photometric errors, we have excluded stars with very large, and very small  $m_{F275W} - m_{F814W}$  and  $C_{F275W, F336W, F438W}$  values. We will use the same colour code in Fig. 6.

Milone et al. (2013) have shown that RGB stars with both extreme  $m_{F275W} - m_{F814W}$  and  $C_{F275W, F336W, F438W}$  values are the progeny of MS stars with correspondingly extreme  $m_{F275W} - m_{F814W}$  and  $C_{F275W, F336W, F438W}$ . According to this scenario, the cyan and green stars selected in Fig. 5 correspond to the groups of stars that have been defined as  $A_{IV}$  and  $A_{II}$ , respectively, along the RGB (see lower-left panel of Fig. 4). The majority of both MS-A and RGB-A stars are clustered at intermediate  $\Delta_{F275W, F814W}^N$  and  $\Delta_{C_{F275W, F336W, F438W}}^N$

<sup>2</sup>The  $m_{F275W} - m_{F814W}$  error has been estimated as  $\delta(m_{F275W} - m_{F814W}) = \sqrt{\delta(m_{F275W})^2 + \delta(m_{F814W})^2}$ , where  $\delta(m_{F275W})$  and  $\delta(m_{F814W})$  are the rms of magnitude measurements from the six  $F275W$  and five  $F814W$  exposures, respectively, divided by the square root of the number of images minus one.

**Table 1.** Fraction of stars, and summary of the main properties of the seven stellar populations of M2 used throughout this work. As discussed in this paper the values of [Fe/H], [Na/Fe], and [ $\alpha$ /Fe] are derived from Y14. The last two columns indicate the section and the figure where the populations have been identified along the RGB and the MS.

POP	Population ratio	[Fe/H] (dex)	[Na/Fe] (dex)	[ $\alpha$ /Fe] (dex)	$Y$ (dex)	age (Gyr)	Sect./Fig. RGB	Sect./Fig. MS
$A_I$	$0.076 \pm 0.028$	-1.7	-	0.4	-	$13.0 \pm 0.75$	4/4	-
$A_{II}$	$0.222 \pm 0.039$	-1.7	-0.16	0.4	0.246	$13.0 \pm 0.75$	4/4	5/5
$A_{III}$	$0.490 \pm 0.048$	-1.7	0.18	0.4	-	$13.0 \pm 0.75$	4/4	-
$A_{IV}$	$0.173 \pm 0.036$	-1.7	0.35	0.4	0.315	$13.0 \pm 0.75$	4/4	5/5
$B_I$	$0.014 \pm 0.003$	-1.5	0.15	-	-	-	4/3	-
$B_{II}$	$0.015 \pm 0.003$	-1.5	0.55	-	-	-	4/3	-
$C$	$0.010 \pm 0.002$	-1.0	-0.15	0.2	0.248	$12.0 \pm 0.75$	4/3	5/6

values and are the progenitors of group  $A_{III}$  in the RGB (Fig. 4). The present data set does not allow us to identify the progenitors of RGB- $A_I$  along the MS.

The extreme  $\Delta_{F275W, F814W}^N$  and  $\Delta_{C, F275W, F336W, F438W}^N$  values of the  $A_{II}$  and  $A_{IV}$  stellar groups imply that they must have extreme contents of helium and light elements. In the next section, we will estimate the helium spread within MS-A. We remind the reader that both the  $m_{F275W} - m_{F814W}$  colour and the  $C_{F275W, F336W, F438W}$  index are sensitive to light-element abundances such as OH, CN, NH, CH molecules of different strength affect the flux in the  $F275W$ ,  $F336W$ ,  $F438W$  filters. As expected, the three groups of RGB-A stars in M2, which are clearly distinguishable in Fig. 4, are more confused along MS-A. This is both due to the photometric errors and to a temperature difference, as the MS stars are hotter than the RGB. As a consequence, light-element variations have a lower influence on the photometric passbands used in our study, due to the diminished strengths of the OH, CH, and CN molecular bands (see Sbordone et al. 2011; Cassisi et al. 2013).

## 6 AGE AND HELIUM CONTENT OF THE STELLAR POPULATIONS

Y14 have determined abundances for 34 elements for 16 M2 red giants, thus providing an accurate chemical pattern of the multiple stellar populations of M2. In the following, we will use their measurements to constrain age and helium-abundance differences among stars in M2. The left-hand panel of Fig. 6 shows the  $m_{F814W}$  versus  $m_{F606W} - m_{F814W}$  CMD of M2 from ACS/WFC photometry (Anderson et al. 2008). MS-C stars are highlighted with aqua diamond symbols.

In order to measure the age and helium content, we have used the photometry from the  $F606W$  and  $F814W$  bands, as it is not significantly affected by the light-element abundance variations (Sbordone et al. 2011; Milone et al. 2012b). A set of isochrones from Dotter et al. (2007) corresponding to different chemical composition and ages has been superimposed on the CMD of Fig. 6. We have used a primordial-helium ( $Y = 0.246$ ) isochrone (solid black), with metallicity and  $\alpha$ -element content as in Y14 ([Fe/H] = -1.7, [ $\alpha$ /Fe] = 0.4) to fit population  $A_{II}$ .

To do this, we compared the CMD with a grid of isochrones with the same composition but different age, distance modulus, and reddening. The best fit corresponds to an apparent distance modulus  $(m - M)_V = 15.55$ , age  $13.0 \pm 0.75$  Gyr, and  $E(B - V) = 0.07$ , in agreement with values from the Harris (1996, 2010 update) catalogue. Reddening has been converted into absorption in the ACS/WFC  $F606W$  and  $F814W$  band as in Bedin et al. (2005). We assumed the same values of reddening and distance modulus for

the other isochrones of Fig. 6. The best-fitting age was estimated as in Dotter et al. (2010) by determining the isochrone that best fit the CMD in the region between the MS turn-off and the SGB. The corresponding uncertainty was inferred from the intrinsic magnitude and colour spread of the MS turn-off and the SGB stars and we considered as  $1\sigma$  uncertainty the range of age that envelope the bulk of these stars (see Dotter et al. 2010 for details).

The aqua and the yellow isochrones both have age 12.0 Gyr, primordial helium, and the same iron abundance as measured by Y14 ([Fe/H] = -1.0) for population C, but different  $\alpha$ -element content. The aqua isochrone corresponds to [ $\alpha$ /Fe] = 0.2, consistent with spectroscopic measurements by Y14, and provides the best fit to population C. The best-fitting age has been inferred as described above for population  $A_{II}$  and its uncertainty corresponds to 0.75 Gyr.

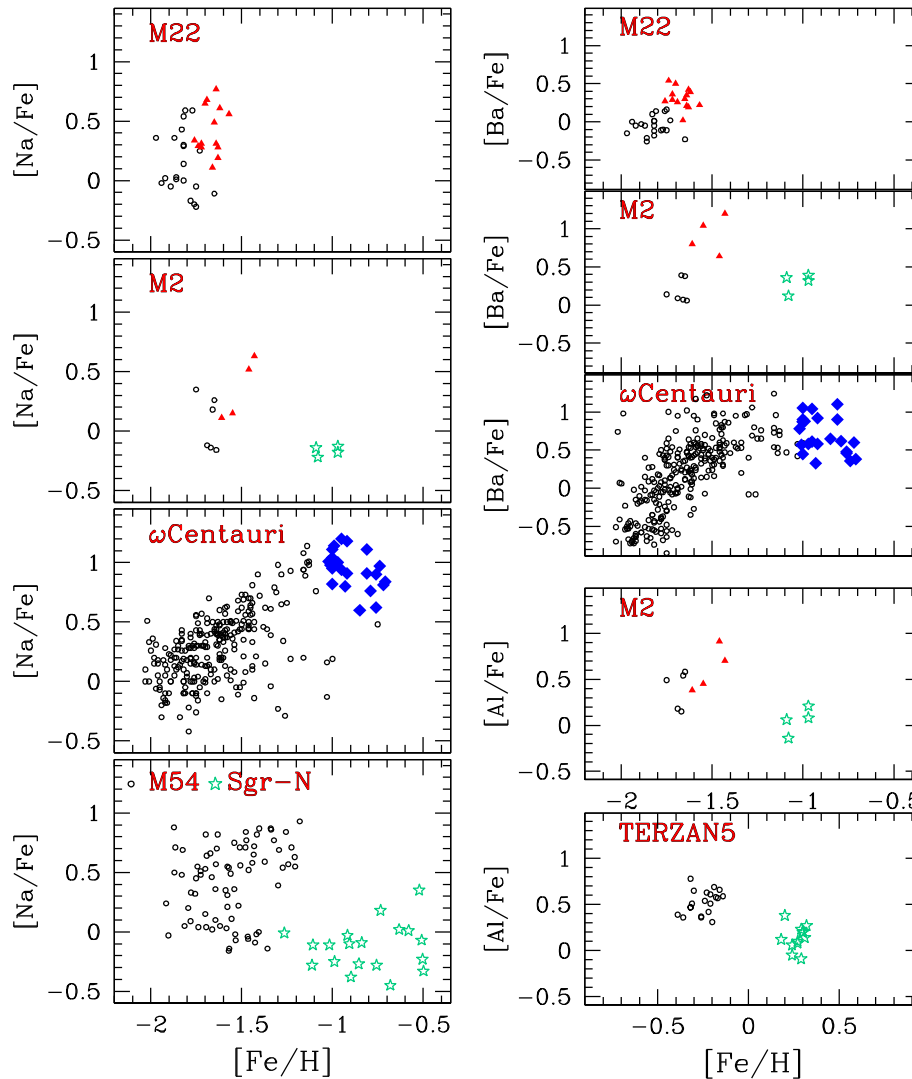

As a consequence, populations A and C are consistent with being coeval within  $\sim 1$  Gyr and with having almost primordial helium content. For completeness, we also plot a metal-rich and helium-rich isochrone ( $Y = 0.33$ , blue line). This isochrone crosses the metal-poor one at  $m_{F814W} \sim 18.8$ , and gets bluer than it towards fainter magnitudes. The fact that population-C stars have redder  $m_{F606W} - m_{F814W}$  colours than the bulk of M2 stars at the same luminosity further supports our conclusion that the population C is not consistent with being significantly helium enhanced.

In the upper-right panel of Fig. 6 green and cyan colour codes mark the two stellar groups  $A_{II}$  and  $A_{IV}$  of MS stars that we identified in Fig. 5. The corresponding fiducial lines have been represented with the same colours. It is clear that MS- $A_{II}$  stars are redder than stars in the MS- $A_{IV}$ .

In the lower-right panel, we have superimposed on to the fiducial lines defined in the upper-right panel the metal-poor isochrones from the left-hand panel, using the same distance modulus and reddening. Population  $A_{II}$  is well fitted by an isochrone with primordial helium ( $Y = 0.246$ , black continuous isochrone), [Fe/H] = -1.7, and [ $\alpha$ /Fe] = 0.4. Population  $A_{IV}$  is reproduced by an isochrone corresponding to a stellar population with the same age, and the same content of iron and  $\alpha$ -elements as  $A_{IV}$ , but with enhanced helium ( $Y = 0.315$ , black dashed line). We obtain the same result when we adopt BaSTI isochrones (Pietrinferni et al. 2004, 2006). The age and helium content of stellar populations inferred from isochrone fitting are summarized in Table 1 together with the values of metallicity, [ $\alpha$ /Fe] and [Na/Fe] used in this paper, and with the fraction of stars within each sub-population.

## 7 COMPARISON WITH OTHER CLUSTERS

In order to better understand the properties of the seven sequences photometrically identified in M2, in this section we will combine

**Figure 7.** Left:  $[\text{Na}/\text{Fe}]$  versus  $[\text{Fe}/\text{H}]$  for four GCs with intrinsic variations in metallicity: M22 (Marino et al. 2011b); M2 (Y14);  $\omega$  Centauri (Marino et al. 2011a); M54 and the Sgr dwarf galaxy (Carretta et al. 2010a). Right: the three upper panels show  $[\text{Ba}/\text{Fe}]$  against  $[\text{Fe}/\text{H}]$  for M22 (Marino et al. 2011b); M2 (Y14);  $\omega$  Centauri (Marino et al. 2011a), while the two lower panels show  $[\text{Al}/\text{Fe}]$  versus  $[\text{Fe}/\text{H}]$  for M2 (Y14) and Terzan 5 (Origlia et al. 2011). The  $s$ -rich stars of M22 and M2 are represented with red triangles, while the blue diamonds mark stars in the RGB-a of  $\omega$  Centauri. Population-C stars of M2, stars in the Sgr dwarf galaxy nucleus, and the metal-rich stars of Terzan 5 are plotted with aqua symbols.

the available spectroscopic information with photometric results. In Fig. 7, we summarize what we currently know about clusters that show an intrinsic variation in iron content. Fig. 7 shows the abundance of sodium, aluminum, and barium versus iron content for five GCs: M2 (Y14), M22 (Marino et al. 2011b), M54 including the Sagittarius (Sgr) dwarf galaxy nucleus (Carretta et al. 2010a),  $\omega$  Cen (Marino et al. 2011a) and Terzan 5 (Origlia et al. 2011). We have represented with red triangles stars of M22 and M2 that are enhanced in  $s$ -processes elements. Stars in the Sgr dwarf galaxy, in the population C of M2, and metal-rich stars of Terzan 5 are plotted with aqua star symbols, while blue diamonds represent stars in the most-metal-rich RGB of  $\omega$  Cen.

Fig. 7 shows that populations A and B of M2 have different content of  $s$ -elements with iron-intermediate stars also being  $s$ -rich (Y14). In addition, Fig. 4 shows that RGB-A and RGB-B stars host stellar sub-populations with different light-element abundance in close analogy with what is observed in M22. Y14 suggested that the populations A and B of M2, and other anomalous GCs (M22,

NGC 1851, and  $\omega$  Cen) have experienced a similar complex star formation history. We refer the reader to papers by Marino et al. (2009, Marino et al. 2011a,b), Carretta et al. (2010a), Da Costa & Marino (2011), Y14 and reference therein for a discussion of this topic.

Y14 noticed that the RGB-C stars of M2 exhibit chemical properties that are rarely observed in any GC. In this section, we focus on the population C of M2 and compare it with the three extreme cases of  $\omega$  Cen, M54, and Terzan 5.

(i)  $\omega$  Cen exhibits a multimodal iron distribution that spans a wide range of metallicity, with  $[\text{Fe}/\text{H}]$  ranging from  $\sim -2.0$  to  $\sim -0.7$  dex (Norris & Da Costa 1995; Johnson & Pilachowski 2010; Marino et al. 2011a; Villanova et al. 2014). The MS is multimodal (Bedin et al. 2004), with three main components: a red MS, which is made of metal-poor and helium-normal stars, a blue MS, which hosts metal-intermediate stars and is highly helium enhanced, by up to  $Y \sim 0.39$ , and a metal-rich MS, named MSa in Piotto et al. (2005).

Bellini et al. (2010) have used multiwavelength *HST* photometry to investigate the multiple MSs in  $\omega$  Cen and showed that MSa stars have redder  $m_{F275W} - m_{F814W}$ ,  $m_{F336W} - m_{F814W}$ , and  $m_{F435W} - m_{F814W}$  colours than the red MS and the blue MS. They also noticed that, when using  $m_{F606W} - m_{F814W}$ ,  $m_{F625W} - m_{F814W}$ , or  $m_{F658N} - m_{F814W}$  colours, MSa becomes bluer than the red MS. Since MSa stars are the progenitors of the RGBa (Pancino et al. 2002), they are significantly more metal-rich than the red MS. Therefore, the blue colours of MSa would imply that its stars are enriched in helium, as suggested by Norris (2004).

M2 is similar to  $\omega$  Cen in having stellar populations that are highly enhanced in iron relative to the others, but there are two important differences: (1) in  $\omega$  Cen, the stars of the most metal-rich population are strongly enhanced in sodium, aluminum and *s*-process elements (Norris & Da Costa 1995; Johnson & Pilachowski 2010; D’Antona et al. 2011; Marino et al. 2011a), in contrast with the population C of M2, where the content of Na, Al, Y, and Zr are comparable with those of first-generation, normal-population stars (Y14, see also Fig. 6). (2) The population C of M2 is not consistent with a high helium abundance. We conclude that  $\omega$  Cen and M2 have certainly experienced a different chemical-enrichment history.

(ii) M54 is another massive GC with star-to-star variations in metallicity (Sarajedini & Layden 1995; Bellazzini et al. 2008; Carretta et al. 2010a,b). It lies in the nuclear region of the Sgr dwarf galaxy, although it is not clear whether it formed *in situ* or was pushed into the centre by dynamical friction. Carretta et al. (2010a,b) have derived chemical abundances for Fe, Na, and  $\alpha$  elements for 103 red giants in the Sgr nucleus (Sgr-N). They used both radial velocities and photometry to identify 76 M54 members and 27 Sgr stars. Carretta and collaborators showed that M54 stars span a wide range in metallicity, with  $[\text{Fe}/\text{H}]$  ranging from  $\sim -1.9$  dex up to  $-1.2$  dex ( $\sigma \sim 0.2$  dex), while Sgr stars are distributed towards higher iron content. In the left-hand panels of Fig. 6, we plotted  $[\text{Na}/\text{Fe}]$  versus  $[\text{Fe}/\text{H}]$  for RGB stars in M54 (black circles) and Sgr (aqua stars) from Carretta et al. (2010b). Stars in M54 exhibit a large star-to-star variation in  $[\text{Na}/\text{Fe}]$ , and, on average, high  $[\text{Na}/\text{Fe}]$ . By contrast, Sgr-N stars exhibit a low sodium abundance (see Fig. 7).

The stellar system including M54 and the Sgr-N shares some similarities with M2. M54 seems to include populations similar to M2’s A and B, while the Sgr-N star chemistry is similar to the abundance pattern of M2 population C. Unlike the case of  $\omega$  Cen, however, where most of the metal-rich stars are strongly enhanced in sodium, both the Sgr-N stars and population C of M2 exhibit low  $[\text{Na}/\text{Fe}]$ . In addition, population C of M2 is depleted in  $[\alpha/\text{Fe}]$  by  $\sim 0.2$  dex, with respect to population A (Y14). This is similar to what observed in the Sgr dwarf galaxy, where the Sgr-N stars have a lower abundance of  $\alpha$ -elements than M54 stars.

(iii) Terzan 5 also exhibits a very peculiar chemical composition with two main groups of stars with  $[\text{Fe}/\text{H}] \sim -0.25$  and  $[\text{Fe}/\text{H}] \sim +0.30$  (Ferraro et al. 2009; Origlia et al. 2011). The group of metal-rich stars has a lower  $\alpha$ -element abundance with respect to the more metal-poor population, thus suggesting that Type Ia SNe may have played a role in the star formation history of this cluster. Noticeably, at odds with the populations A and B of M2, there is no evidence for light-element variations among neither the metal-rich nor the metal-poor stars of Terzan 5. To further investigate similarities between M2 and Terzan 5, we show in the lower-right panels of Fig. 7  $[\text{Al}/\text{Fe}]$  versus  $[\text{Fe}/\text{H}]$ . We note that all the metal-rich stars of both M2 and Terzan 5 have almost-solar aluminum ( $[\text{Al}/\text{Fe}] \sim 0.1 - 0.2$ ), while the metal-poor populations of both clusters host stars with higher aluminum content. A similar pattern has been observed

for M54 and the Sgr-N with the latter having, on average, lower aluminum content.

## 8 SUMMARY AND CONCLUSIONS

We have exploited multiwavelength photometry from the *HST* UV Legacy Survey GO-13297 to investigate the stellar populations of the GC M2. We have identified three main components, which we named A, B, and C. Within these three main components, we identified seven stellar sub-populations.

The main component, A, which includes sub-populations  $A_I$ ,  $A_{II}$ ,  $A_{III}$ , and  $A_{IV}$ , hosts the metal-poor stars identified by Y14. It exhibits an intrinsic spread in helium, with  $Y$  ranging from primordial values ( $Y \sim 0.25$ ) up to  $Y \sim 0.31$  and includes  $\sim 96$  per cent of stars. Noticeably, the three stars with different sodium abundance identified by Y14 are located on the different sequences, with helium-rich stars also having higher  $[\text{Na}/\text{Fe}]$ . Therefore, the component A is similar to the multiple stellar populations we have identified in the majority of GCs. These multiple sequences host stars with the same heavy element abundance, have almost-homogeneous content of *s*-elements, and exhibit star-to-star variations in helium and light elements as expected for material which has been gone through hydrogen burning at high temperatures (CNO cycle).

Component B has intermediate metallicity and includes  $\sim 3$  per cent of stars, is enhanced in neutron-capture elements which are usually associated with *s*-processes in Solar system material, and includes two sub-populations, namely  $B_I$ ,  $B_{II}$ , with a different light-element abundance. It could be the analogous of the *s*-rich and iron-rich stellar population of M22, and shares similarities with the iron-rich stellar populations of  $\omega$  Cen and M54.

Component C includes  $\sim 1$  per cent of stars, is highly enhanced in iron ( $[\text{Fe}/\text{H}] \sim -1.0$ ), and exhibits a lower  $[\alpha/\text{Fe}]$  and  $[\text{Al}/\text{Fe}]$  ratio than populations A and B. Its stars are *s*-poor and are not enhanced in helium. Such properties are not compatible with self-enrichment due to either AGB or fast rotating massive stars and are not consistent with the early-disc accretion scenario.

The combination of the photometric and spectroscopic studies of M2 presented in this paper and in Y14 suggest that M2 is composed by at least two distinct entities. The main one, containing most of the stars in M2, includes populations A and B and can be further separated into six distinct sub-populations. The minor component (population C), which makes up  $\sim 1$  per cent of the cluster stars and apparently has not produced any secondary sub-populations, is populated by stars rich in metals and with *s*-process elements in nearly solar proportion. Due to the chemical properties of population-C stars, one possibility is that population-C stars formed from material that made the first A sub-population but having been slightly contaminated by SNe of either type.

In any event, the component A+B and the component C of M2 must have experienced independent star formation histories, and as an alternative M2 may be final result of the merger of two stellar systems. The fact that M2 shares many similarities with the stellar system composed by M54 and the nucleus of the Sgr dwarf galaxy, makes it very tempting to speculate that it could be the remnant of a much larger stellar system which merged with the Milky Way in the past.

## ACKNOWLEDGEMENTS

Support for *Hubble Space Telescope* proposal GO-13297 was provided by NASA through grants from STScI, which is operated by

AURA, Inc., under NASA contract NAS 5-26555. APM and HJ acknowledge support by the Australian Research Council through Discovery Project grant DP120100475. MZ acknowledges support by Proyecto Fondecyt Regular 1110393, by the BASAL Center for Astrophysics and Associated Technologies PFB-06, and by Project IC120009 ‘Millennium Institute of Astrophysics (MAS)’ of Iniciativa Científica Milenio by the Chilean Ministry of Economy, Development and Tourism.
